Thank you for your assistance.
Cortical activity recorded from experts and non-musicians during guitar playing. No main effect for Bereitschaftspotential amplitude or onset between groups. Negative slope and motor potential components smaller and began later in experts. May indicate reduced activity is required during motor preparation by experts. Training likely to contribute to this more efficient motor preparation.
Differences in cortical activity related to motor planning between experienced guitarists and non-musicians during guitar playing

Abstract

The influence of motor skill learning on movement-related brain activity was investigated using electroencephalography. Previous research has indicated that experienced performers display movement-related cortical potentials (MRCPs) of smaller amplitude and later onset compared to novice participants. Unfortunately, previous studies have lacked ecological validity with experimenters recording the MRCP prior to simple motor tasks and applying the results to more complex motor skills. This study replicated previous research using an ecologically valid motor skill; recording the MRCP from a group of experienced guitarists and a control group of non-musicians whilst they played a simple scale on the guitar. Results indicated no difference between groups in early motor planning. In contrast, the later, negative slope and motor potential components were of smaller amplitude and the negative slope began later in the experienced guitarists. The data may indicate that, for experienced guitarists, a reduced level of effort is required during the motor preparation phase of the task. These findings have implications for musical instrument learning as well as motor skill acquisition in general.

1. Introduction

Performance of most motor skills can be improved by accurate, long-term practice. What occurs within the brain to reflect this improved performance is less clear. Electroencephalography (EEG) can be used to examine movement-related cortical activity with high temporal resolution (Luck, 2005) and, as such, is a suitable technique for investigating changes in cortical activity that may be associated with motor skill learning and performance.

In the final seconds prior to voluntary movement production there is an increase in electrical activity in the motor areas of the brain, known as the movement-related cortical potential (MRCP). One component of the MRCP, the Bereitschaftspotential (BP), is a slowly rising negativity that occurs 1–2 s prior to movement onset (Kornhuber & Deecke, 1965; for a review see Shibasaki & Hallett, 2006). The BP is followed by a steeper gradient negativity, the negative slope (NS'); which occurs at 400–500 ms prior to movement onset (Shibasaki, Barrett, Halliday, & Halliday, 1980). These components are followed by the motor potential (MP), the peak negativity occurring concomitantly to movement onset in contralateral central sites. Both the amplitude and onset times of these components vary depending on the physical and psychological characteristics of the forthcoming movement (Birbaumer, Elbert, Canavan, & Rockstroh, 1990). As such, the MRCP may reflect the cortical activity involved in planning and preparing to perform voluntary movements (Shibasaki & Hallett, 2006). A schematic representation of the pre-movement components of the MRCP is displayed in Fig. 1.

Several studies have investigated differences in the MRCP amplitude and onset times between expert and novice performers to aid our understanding of learning-related changes in brain functioning (e.g., Di Russo, Pitzalis, Aprile, & Spinelli, 2005; Fattapposta et al., 1996; Hatta, Nishihira, Higashiura, Kim, & Kaneda, 2009; Kita, Mori, & Nara, 2001). The main findings from these studies are that expert performers show smaller amplitude and later onset MRCPs than their novice counterparts, prior to task performance. This has been shown in groups of expert and novice clay target (Di Russo, Pitzalis et al., 2005) and pistol shooters (Fattapposta et al., 1996), as well as in elite and novice kendo martial art performers (Hatta et al., 2009; Kita et al., 2001). These authors have generally concluded that experienced performers are able to plan and perform the task with reduced cortical activity compared to novices, attributing these differences to long-term training by the expert group. This body of research is supported by several studies that have used functional magnetic resonance imaging (fMRI) to study skill-related differences in cortical activity in expert and novice musicians. For example, several researchers have reported that expert pianists exhibit reduced activity compared to novices in a variety of movement-related cortical areas when performing actions similar to those used to play the piano (e.g., Haslinger et al., 2004; Jancke,

![Fig. 1. A schematic representation of the movement-related cortical potential (MRCP). Time 0 ms on the horizontal axis indicates the point of movement onset. The pre-movement components, termed the Bereitschaftspotential (BP), the negative slope (NS') and the motor potential (MP) are thought to reflect the cortical activity involved in planning and preparing to perform voluntary movement.](image-url)
Shah, & Peters, 2000; Koenke, Lutz, Wustenberg, & Jancke, 2004; Krings et al., 2000). Krings et al. suggested that this finding may indicate that following long-term practice in a skill, experienced performers require fewer neurons to be active to plan and perform that skill.

Whilst these studies have provided a useful insight into learning-related changes in motor cortex activity, they have tended to employ simple, laboratory-based tasks and applied the results to more complex motor skills. This approach lacks ecological validity as the movement tasks used are far removed from the skill being investigated. For example, simple button pressing was used to investigate clay target shooting (Di Russo, Pitzalis et al., 2005) and pistol shooting (Fattapposta et al., 1996), simple finger tapping was used to study piano or keyboard playing (Haslinger et al., 2004; Jancke et al., 2000; Koenke et al., 2004; Krings et al., 2000), and simple wrist flexion (Kita et al., 2001) and hand-gripping tasks (Hatta et al., 2009) have been used to study kendo. By focusing only on the mechanical actions required to perform a skill, cortical activity involved in other aspects of the skill is not accounted for. Therefore, there is a need to assess differences in the MRCP of expert and novice performers using more ecologically valid motor skills (Nakata, Yoshie, Miura, & Kudo, 2010; Wright, Holmes, & Smith, 2011). Ideally, this would be achieved by measuring cortical activity during performance of the skill being investigated, rather than during performance of a task similar to the skill being investigated. For example, if a study were investigating pistol or rifle shooting, then recording the EEG during shooting performance may be more suitable than recording the EEG using a simple button press task. Similarly, if a study were investigating piano playing, then measuring cortical activity during a piano playing task may provide more meaningful results than recording cortical activity during a simple finger tapping action. Recently, Kristeva, Chakarov, Schulte-Monting, and Spreeër (2003) recorded the MRCP from a group of professional violin players prior to both imagery and physical performance of a short musical sequence on the violin. This indicates that it is possible to record the MRCP prior to ecologically valid motor skills; however, to date, no research has done so in the context of skill learning.

This study aimed to address this gap in the literature by comparing MRCP differences in experienced guitarists and non-musicians using an ecologically valid guitar-playing task. Based on the previously mentioned literature, we predicted that the experienced guitarists would require less cortical activity to plan and control their hand movements when playing the guitar, compared to the non-musicians. Therefore, we expected that the experienced guitarists may require fewer neurons to be active during motor preparation, and so we hypothesised that the experienced guitarists would exhibit smaller amplitude MRCPs that would begin closer to movement onset than the non-musicians, prior to playing a simple scale on the guitar.

2. Methods

2.1. Participants

Ten male, experienced guitar players (mean age 36.5 yrs. ± 13.73) and ten non-musicians (5 male, 5 female; mean age 24.1 yrs. ± 6.57) participated in the study. The experienced guitarists had between 8 and 40 years (mean 18.8 yrs. ± 11.23) of guitar playing experience. They all stated that the guitar was their main instrument and reported that they spent approximately 12.8 (±7.35) hours per week practicing the guitar. The majority of the experienced guitarists played the electric guitar as their primary instrument, although one was an acoustic guitarist. Although not professional musicians, all guitarists had received some form of formal tuition on the guitar, and many of them had experience of playing several other musical instruments. The non-musicians had no prior experience of playing the guitar or any other musical instrument. All participants were right-handed, as assessed by the Edinburgh Handedness Inventory (Oldfield, 1971). All participants gave their written informed consent to take part in the study which was conducted in accordance with the Declaration of Helsinki (2008). The experimental procedures were granted ethical approval by the local institutional ethics committee.

2.2. Electrophysiological recording

Electroencephalography (EEG) was recorded continuously throughout the testing session from six, 6 mm diameter, silver/silver-chloride electrodes positioned over the motor cortex according to the...
International 10-10 system of electrode placement (Nuwer et al., 1998). Electrodes were placed at sites overlying the hand representations of the left (FC3 & C3) and right (FC4 & C4) motor cortex, as well as over the supplementary motor area (FCz & Cz). The electro-oculogram (EOG) was also recorded from below and adjacent to the left eye to monitor both vertical (VEOG) and horizontal (HEOG) eye movements. All electrodes were referenced to linked mastoids and a ground electrode was placed at Fpz. Prior to electrode attachment the recording sites were gently abraded with NuPrep skin preparation paste (DO Weaver, Aurora, CO, USA). Electrodes were then attached to the scalp using Ten20 conductive EEG paste (DO Weaver, Aurora, CO, USA). Electrode impedances were kept homogenous at, or below, 5 kΩ throughout the experiment. Testing commenced 45 minutes after the electrodes were attached to the scalp to minimise signal drift. After this time, the electrode impedances were re-checked to confirm that the impedance values remained below 5 kΩ. The EEG and EOG were recorded using a NeuroScan Synamps amplifier and Scan 4.3 software (Compumedics Neuroscan, Charlotte, NC, USA) with a gain of 1000 and an A/D sampling rate of 1000 Hz. The bandpass filter for the cortical channels was set at 0–30 Hz, whilst the bandpass filter for the EOG channels was set at 0.15–30 Hz.

2.3. Task description

Participants were required to perform 100 repetitions of the first seven notes of the G Major scale (see Fig. 2) on a Yamaha Pacifica 112 V electric guitar. The participants were seated and instructed to play in time with a metronome set at 100 beats per minute (bpm). The G Major scale played at 100 bpm was chosen on the recommendation of an assessor from the ‘Rockschool’ rock and pop music examination board. The G Major scale played at this tempo is a ‘Rockschool’ Grade 2 guitar assessment piece (Rockschool, 2008). After consultation with the assessor, it was expected that this task would be easy for the experienced guitarists to play, whilst still being achievable for the non-musicians with some practice. The metronome ran continuously throughout the experiment and participants were free to initiate each performance of the scale at their own choosing. They were, however, instructed to leave approximately ten seconds in between each repetition of the scale. As the non-musician group had not previously played the scale, they were provided with 15 minutes of instruction on how to play the scale prior to the testing session. To reduce the number of artefacts in the EEG recording, participants were asked to keep as still as possible and to refrain from tapping their feet or nodding their head in time with the metronome. Similarly, they were also instructed to try to avoid blinking immediately prior to and during performance of the task.

Following the 100 repetitions, the guitar was connected to an Apple Mac Mini computer (Apple, Cupertino, CA, USA) and participants performed a further 20 repetitions of the scale in time with the metronome whilst guitar performance was recorded using Logic Express version 9 software (Apple, Cupertino, CA, USA). This allowed each participant’s performance to be assessed offline. It was not possible to have concurrent EEG recording as connecting the guitar to the computer introduced too much electrical interference into the EEG trace. Task performance was measured by ability to play at the correct tempo and variability in performance.

Fig. 2. The G Major scale as played on the guitar, displayed in both the treble clef and tab format. Participants played the first 7 notes, highlighted within the black box, at a tempo of 100 beats per minute. In tab format, the horizontal lines represent each of the six strings on the guitar. The bottom line represents the bottom E string (the thickest string) and the top line represents the top E string (the thinnest string). The numbers depict which fret the string should be pressed down at to successfully play the note.

2.4. Data analysis

The EEG trials were averaged with reference to movement onset. This was recorded by a thin electrode that was attached to the neck of the guitar, underneath the strings on the 3rd fret and plugged into a ‘movement onset’ electrode channel in the EEG amplifier. When the bottom E string was pressed down at the 3rd fret to play the first note of the scale, the string made contact with the electrode, causing a sharp deflection to occur on the ‘movement onset’ channel in the EEG trace. Digital markers were inserted in the EEG recording at the points where the sharp deflection caused by the first note being played exceeded 50 μV in amplitude. An offline computerised eye-movement rejection was then run on the raw data to remove any segments of the EEG that contained artefacts in excess of 50 μV in either the VEOG or HEOG channels. On average 15 trials per participant were rejected from the non-musician group and 19 trials per participant were rejected from the experienced guitarist group as they contained eye-movement artefacts. Following the automated EOG rejection, the data was visually scanned and any additional artefacts in the recording were removed. Movement artefacts were very rare as only the pre-movement components of the EEG were analysed. Using Scan 4.3 software, the EEG recording was then filtered offline with a 0–5 Hz bandpass to remove the higher frequency signals. Following this the EEG was split into epochs of 3 seconds around the movement onset marker (2500 ms prior to and 500 ms after movement onset). The epochs were then averaged together to produce the MRCP. Prior to analysis the microvolt values were converted into z-scores, referenced to a baseline period from t = 2500 ms to t = 2000 ms. The purpose of this was to normalise the data and remove any variability in the baseline data between participants.

For statistical analysis the mean amplitudes and onset times of the BP and NS’, together with the peak amplitude of the MP were extracted from the averaged EEG prior to movement onset at electrode sites FCz, C3, C4 and Cz. MRCPs were not present in all participants at FC3 and FC4 and so these sites were not included in the analysis. The BP amplitude was taken as the mean amplitude from the point of BP onset to the point of NS’ onset, and the NS’ amplitude was taken as the mean amplitude from the point of NS’ onset to the MP peak. The MP was taken as the maximum negative peak immediately prior to movement onset. The BP and NS’ onset times were established by visual inspection by the first author. Using Scan 4.3 software, it was possible to place a cursor marker at the points of BP and NS’ onset and obtain an exact millisecond value at each cursor placement. These onset times were then subsequently confirmed independently, and under blind conditions by the fourth author using the same procedure. Statistical analysis was performed using the SPSS for Windows 15.0 statistical package. The onset times of the BP and NS’ and the mean amplitudes of the BP, NS’ and MP components were submitted to separate 2 group (guitarists, non-musicians) X 4 electrode (FCz, C3, Cz, C4) independent measures analysis of variance (ANOVA). Bonferroni’s post-hoc analysis was used to interpret main effects, whilst the Tukey post-hoc analysis was used to interpret interaction effects.

Ability to play at the correct tempo was measured using Logic Express software. By measuring the millisecond timing error between the beat of the metronome and the notes being played, it was possible to establish synchronicity with the metronome. Variability in performance was calculated using intra-individual coefficients of variation for each participant. This was done by dividing the standard deviation of the performance timing errors by the mean performance timing errors. These two performance measures were then submitted to the appropriate parametric or non-parametric test. All significant effects were reported at an alpha level of .05 and adjusted where necessary.

3. Results

3.1. Electrophysiological data

A clear MRCP, in which the BP, NS’ and MP components were evident was found in both groups, peaking at electrode site Cz. MRCP components were slightly larger on left, compared to right hemisphere electrodes, confirming the contralateral topography of these components (relative to the participants handedness). Waveforms of the MRCP recorded from both groups at all electrode sites

**Fig. 3.** Movement-related cortical potential (MRCP) waveforms, recorded from the motor cortex, for experienced guitarists (black) and non-musicians (red), whilst performing the G Major scale on the guitar at a tempo of 100 beats per minute.

**Fig. 4.** Mean amplitude values of the BP, NS', and MP components of the MRCP for experienced (grey) and novice (black) guitarists. Data was recorded from electrode sites FCz, Cz, C3 and C4, prior to performance of the G Major scale on the guitar. Significant differences between the groups are indicated by stars (*).
215 3.1. Bereitschaftspotential (BP)
216 The BP initiated around 1900 ms prior movement onset and was of similar amplitude in both
217 groups until around 700 ms, when the waveform became more negative in the non-musicians.
218 The onset times of the BP component in both groups are shown in Table 1. The ANOVA for BP onset
219 time revealed no significant differences between groups, $F(1, 18) = 1.63, p = .22$, or between electrodes,
220 $F(2.4, 43.1) = 0.82, p = .46$. However, there was a significant group $\times$ electrode interaction effect for BP
221 onset, $F(2.4, 43.1) = 3.77, p = .02$. Tukey’s HSD post-hoc analysis indicated that the BP onset at Cz and
222 C4 occurred later in the non-musicians than in the experienced guitarists.
223 The amplitude of the BP was taken as the mean amplitude from the point of BP onset to the point of
224 NS' onset. The mean z-score BP amplitude in the experienced guitarist group was $2.34 (\pm 2.56)$ com-
225 pared to $2.44 (\pm 2.29)$ in the non-musicians. The ANOVA revealed no significant difference in terms of
226 BP amplitude between groups, $F(1, 18) = 0.01, p = .92$, or between electrodes, $F(3, 54) = 2.64, p = .06$.
227 Similarly, there was no Group $\times$ Electrode interaction effect, $F(3, 54) = 1.45, p = .24$.

228 3.1.2. Negative slope (NS')
229 The onset times of the NS' component in both groups are shown in Table 1. The ANOVA revealed a
230 significant main effect for group, with a significantly later NS' onset in the experienced guitarists com-
231 pared to the non-musicians, $F(1, 18) = 9.78, p = .006$. No significant main effect was found for NS' onset
232 time between electrodes, $F(1.9, 34.3) = 1.18, p = .32$, and there was no group $\times$ electrode interaction
233 effect, $F(1.9, 34.3) = 1.54, p = .23$.
234 The amplitude of the NS' was taken as the mean amplitude from the point of NS' onset to the MP
235 peak. The mean z-score amplitude for the NS' was $-5.41 (\pm 5.02)$ in the experienced guitarists, com-
236 pared to $-10.45 (\pm 6.22)$ in the non-musicians. The ANOVA revealed a significant main effect for group,
237 with a significantly lower amplitude NS' component in the experienced guitarists compared to the
238 non-musicians, $F(1, 18) = 5.43, p = .03$. There was also a significant difference in the amplitude of
239 the NS' between electrodes, $F(3, 54) = 6.26, p = .001$. Bonferroni’s post-hoc analysis indicated that
240 the NS' amplitude at Cz was significantly larger than at FCz. Finally, there was no group $\times$ electrode
241 interaction effect, $F(3, 54) = 2.2, p = .10$.

242 3.1.3. Motor potential (MP)
243 The amplitude of the MP was taken as the maximum negative peak immediately prior to move-
244 ment onset. The mean z-score amplitude for the MP peak was $-7.48 (\pm 5.28)$ in the experienced gui-
245 tarists, compared to $-16.17 (\pm 8.36)$ in the non-musicians. The ANOVA confirmed that this was a
246 significantly lower amplitude in the experienced guitarists compared to the non-musicians,
247 $F(1, 18) = 10.85, p = .004$. There was also a significant difference in MP peak amplitude between elec-
248 trodes, $F(3, 54) = 7.02, p < .001$. Bonferroni’s post-hoc analysis indicated that, as with the NS', the
249 amplitude of the MP peak was significantly larger at Cz than at FCz. Finally, there was also a significant
250 group $\times$ electrode interaction, $F(3, 54) = 2.97, p = .04$. Tukey’s post-hoc test indicated that the MP
251 amplitude was smaller in experienced guitarists, compared to non-musicians at all electrode sites.

252 3.2. Performance data
253
254 3.2.1. Ability to play at the correct tempo
255 The experienced guitarists were able to play the scale in time with the metronome with an average
256 of 46 ms ($\pm 77$) error between the beat of the metronome and the note being played, compared to

---

Table 1
Mean ($\pm$SD) onset times (ms) for BP and NS' components of the MRCP in experienced and novice guitarists, together with $p$ values from the ANOVA analysis. A separate ANOVA was conducted for each component of the MRCP.

573 ms (±1084) error in the non-musician group. Due to the large variability in performance by the non-musician group (see the high standard deviation value), the assumption of homogeneity of variance was violated. Given this violation, it was deemed more appropriate to analyse these data using a non-parametric Mann–Whitney U test. The results of this test indicated that the experienced guitarists were able to play the scale more closely in time with the metronome than the non-musicians (U = 11, p = .002).

3.2.2. Variability in performance

The mean intra-individual coefficient of variation for the experienced guitarists was 0.73 (±0.1), compared to 1.09 (±0.41) in the non-musicians. An independent t test confirmed that the experienced guitarists were significantly less variable in their performance errors compared to the non-musicians (t = −2.67, df = 9.97, p = .02).

4. Discussion

The aim of this study was to investigate possible differences in the pre-movement components of the MRCP between experienced guitarists and non-musicians in an ecologically valid guitar-playing task. To the best of our knowledge, this study provides the first account of differences in the MRCP between two groups of differing skill levels, prior to performance of an ecologically valid motor skill. We found no group differences in the amplitude of the BP component, although the BP was found to start earlier in the non-musicians at Cz and C4. The amplitude of the NS' component was significantly smaller and began significantly later in the experienced guitarists compared to the non-musicians. In addition, the amplitude of the MP peak was significantly smaller in the experienced guitarists compared to the non-musicians. Previous research has reported the BP, NS' and MP components of the MRCP to be of smaller amplitude and later onset in elite performers compared to novices (Di Russo, Pitzalis et al., 2005; Fattapposta et al., 1996; Hatta et al., 2009; Kita et al., 2001). Therefore, only the NS' and MP findings in this study support those of previous research. Deecke (1996) suggested that negativity in the EEG indicates increased activity in the area of the cortex under study. Based on this suggestion, we propose that the lower negativity prior to movement production in the experienced guitarists, compared to the non-musicians, indicates less activity, and possibly a reduced effort involved in cortical motor preparation. Furthermore, the later onset of this activity for the NS' provides evidence to support the idea of a greater efficiency during motor preparation in experts.

It is interesting to highlight that, as predicted, the reduced cortical activity during motor preparation in the experienced guitarists was also accompanied by superior performance in the task. The experienced guitarists were able to play the scale more closely in time with the metronome than the non-musicians and the significantly smaller variability coefficient in the experienced guitarists suggests that their performance was more stable than the non-musicians were. This finding is consistent with the study by Fattapposta et al. (1996), who reported that expert pistol shooters produced smaller amplitude MRCPs than a novice control group, and also performed better in a shooting-based task. We believe that this performance data strengthens the claim that lower amplitude MRCPs in expert performers are skill-related. Where possible, to corroborate this claim, we encourage other cross-sectional MRCP comparison studies to include a performance measure. Also of interest is the finding that the NS' and MP values were significantly larger at Cz than at FCz. This finding was to be expected, as the MRCP is typically maximal at the vertex (Shibasaki & Hallett, 2006).

Previous research in this area has tended to use relatively simple motor tasks and then extrapolated the findings to more complex motor skills. For example, simple button pressing has been used to study clay target or pistol shooting tasks (Di Russo, Pitzalis et al., 2005; Fattapposta et al., 1996), finger-tapping has been used to study piano playing (Haslinger et al., 2004; Jancke et al., 2000; Koencke et al., 2004; Krings et al., 2000), and hand gripping or wrist flexion tasks have been used to study kendo (Hatta et al., 2009; Kita et al., 2001). Recently, there has been a call for more ecologically valid motor skills to be used when studying skill- and learning-related changes in the motor areas of the brain (Nakata et al., 2010; Wright et al., 2011). This study addressed this need as it investigated the MRCP prior to an ecologically valid motor skill on a guitar, as opposed to a more simple motor task.
The smaller amplitude and later onset of the NS', together with the smaller amplitude MP in the experienced guitarists compared to the non-musicians indicates that the experienced guitarists required less cortical activity, and possibly less effort, to plan and perform the task. This finding is consistent with the research that indicates experienced athletes (Di Russo, Pitzalis et al., 2005; Fattapposta et al., 1996; Hatta et al., 2009; Kita et al., 2001) and musicians (Haslinger et al., 2004; Jancke et al., 2000; Koeneke et al., 2004; Krings et al., 2000) require reduced cortical activity during motor planning and preparation. The fact that we replicated these findings using a more ecologically valid motor skill extends the current literature base and adds support to the claims made in earlier studies that the reported differences are due to training in a particular skill.

One unexpected finding in this study was that there were no differences between the two groups in the amplitude of the BP component, and the onset time of the BP occurred later in the non-musicians than the experienced guitarists at sites Cz and C4. This finding is in contrast with previous research that has reported smaller amplitude and later onset BP components in expert, compared to novice performers (Di Russo, Pitzalis et al., 2005; Fattapposta et al., 1996; Kita et al., 2001). It is possible that the contradictory BP evidence presented in our study could be due to the sound generated by the metronome, which ran continuously throughout the experiment at 100 bpm. Although participants were free to initiate each repetition of the scale at their own choosing, they were also instructed to try to keep their playing in time with the metronome. The result of this may have been that the decision to begin each repetition was governed by the metronome, rather than being self-initiated. A study by Di Russo, Incoccia, Formisano, Sabatini, and Zoccolotti (2005) compared components of the MRCP prior to index finger flexion actions that were either self-initiated or externally triggered by a tone. The authors reported that the BP component was absent prior to self-initiated movements but absent prior to the externally triggered movements. It could be argued that the presence of the metronome in our experiment acted as an external trigger for the participants to begin playing the scale. Therefore, in this experiment, the decision to begin a repetition of the scale may have been partially internally triggered and partially externally triggered. The external trigger element may have reduced the BP amplitude and had a confounding effect on our results. As such, it is not possible to speculate as to the cause of the later BP onset at Cz and C4 in the non-musician group. Removing the metronome would have made measuring performance differences between the groups more difficult and more subjective, and so it was important to include the metronome in this study. However, had the metronome not been present we would have anticipated that, consistent with previous research, the amplitude of the BP would have been smaller and may have begun later in the experienced players, compared to the non-musicians.

Alternative explanations for the NS' differences reported in this study could be the result of age and sex differences between the groups, rather than being skill-related. The non-musicians sample contained five males and five females with a mean age of 24.1 (±6.57) years. The sample of experienced guitarists contained ten males with a mean age of 36.5 years (±13.73). However, regarding age differences, a study by Singh, Knight, Woods, Beckley, and Clayworth (1990) compared amplitude and onset time differences in the MRCP between young (20–40 years) or old (54–78 years) participants, prior to unimanual and bimanual button pressing tasks. The authors reported that there were no differences between the groups in either the amplitude or the onset times of any components of the MRCP. Furthermore, and of relevance to our study, the younger group was sub-divided into two further groups; one with an age range of 20–29 years, and one with an age range of 30–40 years. Again, no differences were reported between these groups in any components of the MRCP. It is therefore unlikely that the differences reported here are age-related.

There is no published data regarding sex differences in the MRCP. However, comparison of the MRCP of the five male non-musicians with the five female non-musicians in this study revealed that there was no difference in the MRCP in terms of sex (Sex differences in the MRCP of the non-musicians were compared using separate 2 sex (male, female) × 4 electrode (FCz, C3, Cz, C4) independent measures ANOVAs. No differences were found between sex for the onset times of the BP (p = .10) or NS' (p = .89) components. Similarly, no differences were found between sex for the amplitudes of the BP (p = .08), NS' (p = .67) or MP (p = .93) components. The smaller amplitude and later onset of the NS', together with the smaller amplitude MP in the experienced guitarists compared to the non-musicians indicates that the experienced guitarists required less cortical activity, and possibly less effort, to plan and perform the task. This finding is consistent with the research that indicates experienced athletes (Di Russo, Pitzalis et al., 2005; Fattapposta et al., 1996; Hatta et al., 2009; Kita et al., 2001) and musicians (Haslinger et al., 2004; Jancke et al., 2000; Koeneke et al., 2004; Krings et al., 2000) require reduced cortical activity during motor planning and preparation. The fact that we replicated these findings using a more ecologically valid motor skill extends the current literature base and adds support to the claims made in earlier studies that the reported differences are due to training in a particular skill.

One unexpected finding in this study was that there were no differences between the two groups in the amplitude of the BP component, and the onset time of the BP occurred later in the non-musicians than the experienced guitarists at sites Cz and C4. This finding is in contrast with previous research that has reported smaller amplitude and later onset BP components in expert, compared to novice performers (Di Russo, Pitzalis et al., 2005; Fattapposta et al., 1996; Kita et al., 2001). It is possible that the contradictory BP evidence presented in our study could be due to the sound generated by the metronome, which ran continuously throughout the experiment at 100 bpm. Although participants were free to initiate each repetition of the scale at their own choosing, they were also instructed to try to keep their playing in time with the metronome. The result of this may have been that the decision to begin each repetition was governed by the metronome, rather than being self-initiated. A study by Di Russo, Incoccia, Formisano, Sabatini, and Zoccolotti (2005) compared components of the MRCP prior to index finger flexion actions that were either self-initiated or externally triggered by a tone. The authors reported that the BP component was present prior to self-initiated movements but absent prior to the externally triggered movements. It could be argued that the presence of the metronome in our experiment acted as an external trigger for the participants to begin playing the scale. Therefore, in this experiment, the decision to begin a repetition of the scale may have been partially internally triggered and partially externally triggered. The external trigger element may have reduced the BP amplitude and had a confounding effect on our results. As such, it is not possible to speculate as to the cause of the later BP onset at Cz and C4 in the non-musician group. Removing the metronome would have made measuring performance differences between the groups more difficult and more subjective, and so it was important to include the metronome in this study. However, had the metronome not been present we would have anticipated that, consistent with previous research, the amplitude of the BP would have been smaller and may have begun later in the experienced players, compared to the non-musicians.

ing participants for age and sex is a limitation to the study, we do not think that these factors had a con-

founding effect on the results.

The differences reported in this study indicate that less cortical activity, and possibly less effort, is 

required during movement preparation in a group of experienced guitarists compared to a group of 

non-musicians. It is possible that these differences are brought about by training in the experienced 

guitarists. However, the cross-sectional design of this study does not allow us to verify this claim or 

speculate as to the time course of these changes. It is possible that short-term practice lasting only 

a few hours could bring about a change in the MRCP, whilst it is equally possible that such changes 

could take many months to develop. To better establish if the differences that have been reported 

using cross-sectional designs are due to training in the expert group, future studies should investigate 

MRCP changes within the same participant group (Nakata et al., 2010; Wright et al., 2011). Research 

should focus on studying changes in the MRCP over both a short-term practice period and a longitu-

dinal learning period of weeks or months. A reduction in cortical activity after either a short-term 

practice period or a longer learning period would provide a stronger indication that the differences 

reported here are due to training. Research is currently in progress in our laboratory in an attempt 

to address these issues.

Acknowledgments

The authors would like to thank Dr Martin Blain for his advice regarding how to assess participants’ 

performance, and Grant Rockley for designing the method of marking movement onset through the 

guitar fret. We would also like to thank two anonymous reviewers for their helpful and constructive 

comments to improve an earlier version of this paper.
