Lumbar extension and spinal height/creep

TITLE: Isolated lumbar extension resistance training improves strength, pain, and disability, but not spinal height or shrinkage (‘creep’) in participants with chronic low back pain

Abstract

Objective: Loss of disc height is commonly associated with chronic low back pain (CLBP). Isolated lumbar extension (ILEX) exercise for the lumbar extensors is recommended to treat CLBP and is suggested such exercise might promote disc healing and regeneration. To examine a 12 week ILEX intervention upon indirect determination of disc height and shrinkage through seated stadiometry, strength, pain, and disability

Design: A quasi experimental wait-list controlled design was used. Participants underwent pre testing (T1), a 12 week control period, retesting (T2), a 12 week intervention period, and finally post testing (T3). Nine participants’ with CLBP underwent a control period and intervention period. Seated stadiometry, ILEX strength, pain, and disability were measured at each time point.

Results: No significant repeated measures effects for any seated stadiometry variables occurred. Significant improvement across the intervention period (T2 to T3) was found for strength ($p<0.0001$; ES = 2.42). Change in pain was not significant for repeated effects ($p=0.064$); however, ES for the intervention period (T2 to T3) was moderate (ES = -0.77). Change in disability was significant between time point T1 and T3 ($p=0.037$) and ES for the intervention period (T2 to T3) was large (ES = -0.92). Pain and disability achieved minimal clinically important changes.

Conclusions: This is apparently the first study to examine disc change in vivo after exercise in CLBP. Results of the present study, though supporting ILEX resistance training to improve strength, pain and disability, did not find any effect upon spinal height.

Key Words: Disc; Hydration; Stadiometer; intervertebral disc cartilage
**Introduction**

Chronic low back pain (CLBP) is a highly prevalent\(^1\)–\(^5\), multifactorial condition\(^6\),\(^7\), representing an enormous economic cost worldwide\(^8\)–\(^10\). The intervertebral discs have been suspected a potential source of painful symptoms in LBP for some time\(^11\) with considerable evidence regarding pain-causing mechanisms\(^12\)–\(^13\). Although it may be difficult to attribute specific disc pathologies to CLBP on an individual basis, there are consistent associations of more serious disc abnormalities in those who suffer from CLBP\(^14\)–\(^16\). Adams and Roughley\(^12\) suggest the presence of some degree of degeneration is a physiologic process associated with aging, whereas more severe degeneration and/or structural abnormality may be indicative of a pathological process or injury and more commonly present in those suffering from CLBP. Many studies support the contention that more severe degrees of degeneration and/or structural abnormality are more consistently apparent in participants with CLBP than those who are asymptomatic\(^17\)–\(^21\) in a dose dependent manner\(^22\),\(^23\). Loss of disc hydration and disc height is also commonly considered indicative of degenerative processes as opposed to being age related\(^12\),\(^24\). Even if not all disc abnormalities can be ascribed as the source of LBP, any degenerative changes also heighten the risk for more severe disc degeneration or injury and thus pain and suffering\(^12\),\(^13\). Thus it seems that, as a consistent finding in symptomatic participants, and a potential source of pain symptoms, disc degeneration or injury is a worthwhile factor to consider in treatment of CLBP.

Exercise is a common prescription for those with CLBP; however, the potential for it to specifically promote positive changes in the intervertebral discs is not often considered. It has been suggested that regular movement and exercise of the lumbar spine might counter and perhaps reverse loss in disc hydration\(^25\)–\(^27\). Nelson et al\(^28\) reported that reduction in pain after isolated lumbar extension (ILEX) exercise was similar in all diagnosed conditions including degenerative disc disease. Concerns have been expressed regarding the safety of using exercise such as ILEX when considering disc health\(^29\). However, although disc degeneration can be affected negatively by loading, the potential for a “safe window” of disc loading that may stimulate optimal disc health does exist\(^30\),\(^31\). Indeed the available animal model research appears to suggest its biological plausibility\(^32\). A relatively high magnitude, short frequency and short duration dynamic loading may produce potentially regenerative effects upon the intervertebral disc (including improvements in disc proteoglycan content, matrix gene expression, rate of cell apoptosis and improved fluid flow and solute transport\(^33\)–\(^37\).
ILEX exercise is suggested to be optimal in comparison to other modalities aimed at conditioning the lumbar extensors and provides significant and meaningful improvements in pain and disability. Moreover, as ILEX allows quantification of load and specific application to the lumbar spine it presents a suitable model for examining the effect of controlled loading upon disc condition in CLBP participants. Indeed strength produced through such exercise may affect the overall robustness of the spine to resist loading. ILEX has been shown to produce successful rehabilitation outcomes in participants diagnosed with degenerative discs in addition to participants undergoing lumbar discectomy for disc herniation. Further, it has been applied in occupational settings with success in reducing both injury occurrence and costs associated with injury. However no studies have quantified any change occurring in disc condition in vivo.

As noted, loss of disc hydration and disc height is a common disc abnormality. Disc hydration is often measured via magnetic resonance imaging (MRI), but indirect measurement can be obtained through measures of spinal height using stadiometry. As such, for researchers wishing to examine the effects of potential interventions upon CLBP and associated symptoms such as disc hydration, as well as for clinicians examining changes in their patients, the use of stadiometry may be of value as an outcome measure. A recent study has reported that a custom built seated stadiometer is reliable in measuring changes in spinal height variables including spinal shrinkage. Thus it might be a suitable outcome measures to examine the effect of disc loading through exercise upon disc hydration. Therefore, the aim of the present study was to examine the potential effect of applied loading to the lumbar intervertebral discs through ILEX resistance exercise as measured using seated stadiometry.

Methods

Study Design

A quasi experimental wait-list controlled design was adopted with all participants undergoing pre testing (T1) followed by an initial 12 week control period, before then being retested (T2) and then beginning the 12 week experimental period. Participants were post tested once the experimental period had finished (T3). The study was approved by the ethics committee at Southampton Solent University (SSU) and conducted within the Sport and Exercise Science Laboratories at SSU.

Participants
A convenience sample of 17 participants (males n = 9, females n = 8) were initially identified and recruited by posters, group email and word of mouth from SSU and the surrounding locality. An a priori power analysis was conducted to determine participant numbers (n) in order to detect a moderate treatment effect size (ES), calculated using Cohen’s $d^{0.5}$, of 0.5. Participant numbers were calculated using G*Power. These calculations showed that 9 participants were required to meet the required power of 0.8 at an alpha value of $p \leq 0.05$ for the statistical analyses proposed (see below).

Inclusion criteria were as follows; participants suffer from non-specific low back pain having lasted longer than 12 weeks and have no medical condition for which resistance training would be contraindicated. Exclusion criteria included; participants must have no medical condition for which movement therapy would be contraindicated. These include: acute (not re-occurring) low back injury occurring within the last 12 weeks, pregnancy, evidence of sciatic nerve root compression (sciatica), leg pain radiating to below the knee, paraesthesia (tingling or numbness), current tension sign, lower limb motor deficit, current disc herniation, previous vertebral fractures or other major structural abnormalities. All participants were cleared to exercise prior to involvement in the study by either their General Practitioner or the Chiropractor in the research group.

After pre testing participants underwent a 12 week control period where they were instructed to continue with their daily activities as normal and any treatment or intervention they were currently undertaking. After completion of this 12 week period participants were re-tested and then underwent a 12 week ILEX exercise training intervention. Figure 1 shows the flow of participants through the study.

**Equipment**

Participants’ standing stature (for demographic purposes) and seated stature (for determination of spinal height) were measured using a wall mounted stadiometer (Holton Ltd, Crymych, Dyfed). Details of seated stature measures are below). Body mass was measured using scales (SECA, Germany) and Body Mass Index (BMI) calculated. Isometric strength testing, range of motion (ROM) and training was performed using the MedX Lumbar Extension Machine (MedX Corporation, Ocala, Florida). The ILEX machine has been shown to be reliable in assessing isometric strength at repeated angles in asymptomatic (test-retest correlation across angles tested, $r = 0.81$ to 0.97)\(^32\) and symptomatic participants ($r = 0.57$ to 0.93)\(^33\), and valid in measurement\(^{54,55}\). Pain was measured using a 100 mm point visual analogue scale (VAS)\(^{56}\), and disability measured using the revised Oswestry disability index (ODI)\(^57\). A customised wooden seat in addition to custom built wall mounted
Lumbar extension and spinal height/creep

adjustable postural rods (Figure 2; Southampton Solent University, Southampton) were used with the wall mounted stadiometer for seated stature measurements in order to ensure participants adopted the same posture within the sagittal plane for each retest trial. The details and reliability of this setup has recently been reported elsewhere^49.

**Participant Testing**

All measurements were completed at the same time of day and participants were instructed to avoid heavy lifting for at least two days prior to testing^58. Participants underwent testing for seated stadiometry, and completed two isometric ILEX strength tests on separate days using the MedX Lumbar Extension Machine, at three points throughout the study (T1, T2, and T3). The ILEX test days were separated by at least 72 hours in order to avoid the effects of residual fatigue or soreness. Each test using the ILEX machine involved maximal voluntary isometric contractions at various angles through the participants full ROM in order to measure maximal isometric ILEX strength. The number of angles tested depended on the participants individual ROM. Participants where tested at as many of the following angles as they were able to achieve; 72°, 60°, 48°, 36°, 24°, 12°, and 0°. Details of the full test protocol using the ILEX machine and details of the restraint mechanisms have been documented previously elsewhere^52. At each time point participants were also required to complete the VAS and ODI.

In order to normalise spine height prior to stadiometry measurement the participant was instructed to lie in the supine position for 10 minutes with his or her hands resting on the stomach, head in a neutral position and supported by a pillow, and legs uncrossed with a pillow under the knees for support. A custom set-up (See Figure 2) was used in combination with the wall mounted stadiometer used for standing measurements. Full details of the test protocol are detailed elsewhere^49. Ten repeated measurements were taken as close as possible to every 20 seconds over a period of ~3 - 3.5 minutes with the participant remaining in the stadiometer between measurements^59. From this spinal height for the first measurement, the average of the 10 measurements, total shrinkage (difference between first and last measurement), and the rate of shrinkage across the 10 measurements examined as the slope of the curve when a linear regression was fitted (standard error of measurement were 3.1mm, 2.8mm, 2.6mm and 0.212, respectively). Post testing occurred 1 week after the final ILEX training session.
Participant Training

Training was conducted at a frequency of 1x/week for a period of 12 weeks. This frequency of training has been shown to significantly improve ILEX strength and was chosen over more frequent training due to potential for overtraining when the lumbar extensor muscles are isolated\(^6\). Also a second weekly training session offers no further improvements in symptomatic participants\(^6\). Twelve weeks was the chosen duration as Carpenter et al\(^6\) have demonstrated that strength improvement from ILEX training occurs largely within the first 12 weeks. Participants performed one set of variable resistance ILEX exercise through their full ROM. Resistance load was 80% of max recorded tested functional torque during maximal isometric testing for both groups and repetitions performed until momentary failure in order to control for intensity of effort\(^6\). Repetitions were performed taking at least 2 seconds to complete the concentric phase, holding for 1 second in full extension and taking at least 4 seconds for the eccentric phase. Resistance load was increased by 5% in the next session once the participant was able to continue exercise for over 105 seconds using their current load before achieving failure. All training was supervised by the lead researcher.

Data Analysis

Nine participants’ data (Males, n = 4; Females, n = 5) were available after allowing for attrition. Isometric strength, recorded in units of torque, was measured as foot pounds (ft.lbs\(^1\)) and converted to Newton metres (Nm) using a correction of 1.356. Spinal height was calculated by subtracting the seat height (445 mm) from the stature recorded during seated stadiometry measurement. Because of individual differences between participants for lumbar ROM, ILEX strength data was averaged across all angles tested (ranging from 0\(^0\) to 72\(^0\)). Mauchly’s test for sphericity was used to determine equality of variance for data at \(p>0.05\). The independent variable to examine was the time-point associated with the period (i.e. T1, T2, and T3) and dependent variables were ILEX strength, pain, disability, first measurement of each spinal height trial, average spinal height across the 10 measurements, total shrinkage defined as the difference between the last and first of the 10 measurements (i.e. a negative value represented loss of spinal height), and rate of shrinkage as the slope of the curve fitted using a linear regression model for time and spinal height (a higher value indicating a steeper slope and greater rate of shrinkage). Data with assumed sphericity for participant demographics and dependent variables were subjected to repeated measures ANOVA. Post hoc pairwise comparisons using a Bonferroni adjustment were conducted comparing T1 to T2 (encompassing the control period), T1 to T3 (encompassing both the control and intervention period) and T2 to T3 (encompassing the intervention period). Within participant effect sizes were
calculated using Cohen’s $d^{50}$ for absolute change in the independent variables across T1 to T2 and across T2 to T3 where an ES of 0.20-0.49 was considered as small, 0.50-0.79 as moderate and $\geq$0.80 as large. In addition, changes in pain and disability were compared to consensus standards for minimal clinically important change (MCIC)$^{64}$. Ostelo et al$^{64}$ propose the MCIC for VAS as 15mm and for ODI 10 points. Statistical analysis was performed using SPSS statistics computer package (vs.20) and $p \leq 0.05$ set as the limit for statistical significance.

**Results**

**Participants**

Participant baseline demographics are shown in table 1.

**Seated Stadiometry**

Table 2 shows spinal height results from seated stadiometry testing at each time point. No significant repeated measures effects by time were found for any seated stadiometry variable ($p = 0.542$ to 0.713). ESs between T1 and T2 were 0.23, -0.29, -0.36, and -0.35 for 1st measure, average, shrinkage and slope respectively with all being considered small. ESs between T2 and T3 were 0.07, 0.25, 0.15, and 0.11 with all being respectively considered small or less than.

**ILEX Strength**

Figure 3 shows ILEX strength measured at each time point. A significant repeated measures effect by time was observed for ILEX strength ($F_{(2, 16)} = 26.263, p < 0.0001$). Post hoc pairwise comparisons revealed a significant difference between both T1 and T3 ($p = 0.002$) and T2 and T3 ($p < 0.0001$). ES for between T1 and T2 was -0.34 and considered small. ES for between T2 and T3 was 2.42 and considered large.

**Oswestry Disability Index (ODI) & Visual Analogue Scale (VAS)**

VAS and ODI measures for each time point are shown in table 3. ANOVA failed to achieve significance for repeated measures effect by time for VAS ($F_{(2, 16)} = 3.281, p = 0.064$). A significant repeated measures effect by time was observed for ODI ($F_{(2, 16)} = 6.846, p = 0.007$). Post hoc pairwise comparisons revealed a significant difference between T1 and T3 ($p = 0.037$) for ODI. Changes in VAS and ODI over the control period (between T1 and T2) did not achieve MCICs. Changes in VAS and ODI after the intervention period (between T2 and T3)
both achieved MCICs (reduction of ~16 mm and ~12 pts respectively). ESs for between T1 and T2 were 0.17 and 0.13 for VAS and ODI respectively and considered small. ESs for between T2 and T3 were -0.77 and -0.92 respectively and considered moderate and large respectively.

**Discussion**

The purpose this study was to examine the effects of a 12 week ILEX resistance training intervention in participants with CLBP upon indirect determination of disc hydration through spinal height measured using seated stadiometry. To the author’s knowledge this is the first study to examine, albeit indirectly, whether positive changes in the discs measured *in vivo* result from exercise interventions in participants with CLBP.

Symptomatic degenerative discs show a number of abnormalities including reduced glycosaminoglycans, dehydration, and reduced nucleus pulposus pH. Some have suggested that metabolic abnormalities in the intervertebral disc might be improved, thus potentially halting or reversing the degenerative process, through appropriate exercise of the lumbar spine. The exercise specifically considered by Mooney et al and Mayer et al was ILEX. Not all exercises are equally effective in conditioning the lumbar extensors and ILEX has been suggested recently as optimal for this purpose. Indeed it has been hypothesised that such an exercise intervention might provide a suitable model for examining the potential for controlled loading to improving disc condition also.

Some studies have suggested that continued compressive loading can contribute to harmful responses in the disc in a dose-dependent manner (i.e. magnitude and duration), which might further suggest cause for concern in employing ILEX resistance exercise for those with LBP. However, this dose-dependent mechanism has important implications for ILEX resistance exercise, which is also typically employed in a dose-dependent manner. ILEX rehabilitation is normally employed using a resistance that allows only ~8-12 repetitions and exercise is performed to momentary failure using this resistance, which has been suggested as optimal for strength and hypertrophic adaptations in addition to improving pain and disability. An exercise frequency of once per week has also been identified as sufficient for improving lumbar extension strength, pain and disability. Thus ILEX rehabilitation represents a relatively high loading on the disc though at a low frequency and volume. Walsh and Lotz report that, in comparison to higher frequency and lower load compression, lower frequency and higher load compression induces positive improvements in disc proteoglycan.
content, matrix gene expression and rate of cell apoptosis. Thus there may be potential for ILEX rehabilitation
to exert a similar adaptive effect. Indeed, Maclean et al\textsuperscript{34,35} have also showed that anabolic and catabolic
responses in the nucleus are dependent upon load and frequency with anabolic genes being stimulated at low
frequencies and catabolic genes being stimulated at higher frequencies. They also revealed that very low loading
had no effect upon gene expression suggesting that some degree of loading, though at a low frequency, is
required to stimulate an adaptive anabolic response.

These studies have examined what might be considered regenerative processes, but as we have highlighted, a
loss of disc hydration is also present in degenerative discs\textsuperscript{65} and so rehydration may also be an important
consideration. Ferguson et al\textsuperscript{36} have shown that loading increases fluid flow across the disc, which in turn also
enhances transport of larger solutes into the intervertebral disc. Some authors have suggested ILEX
rehabilitation may enhance pressure variance across the disc through its flexion-extension cycles and thus
enhance interstitial fluid flow\textsuperscript{26,27,61}. The findings of Ferguson et al\textsuperscript{36} would lend biological plausibility to this
potential mechanism also. Further, Wang et al\textsuperscript{37} have presented that while static loading contributes to catabolic
activity, dynamic compressive loading contrastingly promotes anabolic activity.

Research thus far has been conducted using in vitro animal models. This study is apparently the first to attempt
to examine the chronic effects of specific loading upon the disc in vivo. Due to suggestions from other authors
regarding use of ILEX to ‘rehydrate’ the discs\textsuperscript{25,26} and that loading increases fluid flow, enhancing transport of
larger solutes into the intervertebral disc\textsuperscript{36}, it was considered that ILEX may create pressure variance across the
disc through flexion-extension cycles and thus enhance interstitial fluid flow. Thus it was hypothesised a 12
week ILEX resistance training intervention in CLBP participants would improve disc hydration as measured
indirectly through spinal height measures using seated stadiometry.

However, the results of the present study suggested that, although the 12 week intervention improved ILEX
strength, pain and disability, there was no change in any of the seated stadiometry variables measured. Seated
stature measures did not achieve significance, ESs were all small or less than, and were also within the between-
day range of error determined for the custom seated stadiometry set-up used\textsuperscript{49}. Our sample estimate was based
on the detection of an ES of at least 0.5 and so the lack of change may be the result of a type II error. As no
other study has examined the effects of an intervention upon chronic adaptation in the discs in vivo it is not
possible to discern whether these results truly reflect a lack of change from the intervention or whether they stem from the testing utilised.

Acute studies of stature changes from various loading conditions reveal a wide range of changes some of which the current set-up used may have been sensitive enough to detect: \(~0.5\text{mm}^{70}, ~3\text{mm}^{71}, ~5\text{mm}^{48}, ~7.5 - 10\text{mm}^{72}\), and \(~6-7\text{mm}^{73}\). Considering the possible magnitudes of acute differences detected by some of these studies, it may be that the ILEX intervention merely did not induce any change in hydration of the discs, or at least not of a sufficient magnitude to be detected. MRI is more sensitive in detecting changes in disc hydration, in particular due to the ability to examine individual discs, as opposed to the cumulative total of their height, including the vertebral bodies and other oseoligamentous structures, when using seated stadiometry. Kourtis et al\(^{48}\) report an error when using MRI of \(~0.5\text{mm} \) which is considerably lower than the error within seated stadiometry including our custom seated stadiometry set-up (3.1mm). Further study should examine whether changes in disc hydration occur from exercise based interventions when tested using MRI. Whether or not such small changes in disc hydration, if indeed they occur as a result of ILEX resistance training, are meaningful or not is yet to be determined. However, loss of hydration is only one aspect of a range of possible factors indicating disc condition\(^{12}\) and so, though there may not be a change in disc hydration after exercise interventions, the potential mechanisms of adaptation might impart positive adaptation in other features of the disc. Additional categorisation of disc condition would be a further benefit of follow-up study utilising MRI.

A further aspect examined in the present study was the time dependent loss of stature, or shrinkage, related to spinal loading. This is considered an indicator of spinal ‘creep’ due to its visoelastic properties and may reflect the potential for spinal structures to experience time related changes in biomechanical stresses\(^{72,74}\). Indeed stature shrinkage from constant static loading differs between asymptomatic controls and CLBP participants\(^{75}\) and prior work has found a relationship between trunk extension strength and stature loss\(^{40}\). This study examined change in spinal height and rate of shrinkage due to the participants own upper body mass over a 3 – 3.5 minute test where the participant remained seated in the stadiometer. The between-day reliability of this variable in our custom set-up\(^{49}\) was similar to that reported by others\(^{76}\). However, as with measurements of stature, there was no significant change in shrinkage or rate of shrinkage after the ILEX intervention and ESs were small or less than suggesting there was no chronic change in the visoelastic properties of the spine.
Lumbar extension and spinal height/creep

Despite absence of changes in seated stadiometry variables in response to the intervention, changes were observed for ILEX strength, pain and disability. No changes in any variables were found over the 12 week control period. However, ILEX strength increased significantly over the intervention period and to a similar degree (~34%) as other studies utilising the same intervention\(^\text{61,77}\). These results also indicated the ILEX intervention period resulted in a significant reduction in disability measured using the ODI between baseline (T1) and re-test after the intervention period (T3). Though change in pain and disability over the intervention period did not achieve significance they were similar to other studies utilising the same ILEX intervention in CLBP participants\(^\text{61,77}\) and thus likely reflect the studies small sample size and thus a type II error. Indeed despite this, change in pain and disability across the intervention period using VAS and ODI did both achieve MCICs (reduction of ~16 mm and ~12 pts respectively), ESs were moderate to large, and therefore can be considered meaningful.

One limitation of the present study was the relatively high average age of the sample population. This may have meant that age related changes were present in the discs which are suggested to be more difficult to reverse than producing healing of degenerated discs\(^\text{13}\). Thus future study, in addition to considering utilisation of MRI to detect *in vivo* changes in disc condition, should also utilise a larger sample size of younger adults. Further, the duration of the intervention (12 weeks), though sufficient for inducing changes in tissues such as muscle, may be insufficient for inducing changes in the disc due to the particularly slow turnover rates of collagen and proteoglycans\(^\text{78,79}\). Additional work in this area might thus consider the investigation of interventions of longer duration.

The utility of the intervention should also be considered in context. A minimal approach such as ILEX also offers the benefit of time efficiency. ILEX sessions require at least ~50% less time compared to regular physical therapy\(^\text{80}\). Recent analysis suggested greater benefit may occur with a greater frequency of exercise sessions (an additional eight sessions required to improve VAS scores by 1mm compared to controls\(^\text{81}\)). ILEX specifically, however, is highly effective using only a single weekly session with no further benefit from additional sessions\(^\text{61}\). It seems that ILEX is also as effective as either part of a multifaceted intervention or as a standalone approach\(^\text{39}\) and that the benefits can occur from as little as one session per week taking approximately 10-15 minutes with only 1-2 minutes of that comprising exercise. As one of the biggest economic losses through
CLBP is due to work hours lost, both through treatment and absenteeism, a workplace strengthening program using ILEX could be a promising occupational approach.

Conclusions
In conclusion, the results of the present study, though further supporting the use of ILEX resistance training to improve ILEX strength, pain and disability, did not find any effect upon spinal height or shrinkage measures using seated stadiometry. Thus, despite its impact upon other aspects of the multifactorial nature of LBP, suggestion that ILEX exercise improves disc condition in CLBP participants is presently not supported and remains a hypothesis requiring further study.

Authors Contributions
JS, SBL, DS and DJ conceived and designed the experiments; JS performed the experiments; JS analysed the data; NO contributed analysis tools; JS drafted the manuscript; SBL, DS, DJ and NO reviewed and provided critical feedback regarding the manuscript.
