Abstract

This paper presents 170 Schmidt Hammer exposure ages from moraine boulders and glacially-sculpted bedrock to reveal the post-Last Glacial Maximum (LGM) history of the Wicklow Mountains, Ireland. These data suggest that large ice masses survived for 4-7 ka after retreat of the Irish Sea Ice Stream and were sustained by summit ice-fields until ~16.6 ka. Post-LGM retreat was dynamic, with re-advance moraines deposited in response to Heinrich Stadial 1. However, these events reflect short-term ice front oscillations (≤ 1 ka) during the long-term retreat phase. Retreat from re-advance positions was synchronous across the range and paced by climate, with time-progressive deglaciation from low to high elevation. In contrast, marked asynchronicity in the timing of Younger Dryas deglaciation is closely linked to snow redistribution and indicates that for small cirque glaciers (≤ 1 km²), topography can exert the primary control on glacier survival. This result has important implications for palaeoclimate reconstructions as cirque glacier dynamics may be unrelated to climate. This is further complicated by post-depositional processes which can result in moraine ages (e.g. ¹⁰Be) which post-date retreat. Future palaeoclimate studies should prioritise cirque glaciers where snow contributing areas are small and where post-depositional disturbance is limited (matrix-poor, boulder-rich moraines).

Introduction

Recent studies have focused on the retreat dynamics of the Irish Sea Ice Stream (ISIS) (Chiverrell et al., 2013; Smedley et al., 2017a), a major outlet of the British-Irish Ice Sheet (BIIS; Smedley et al., 2017b). The timing of ISIS retreat after the Last Glacial Maximum (LGM; 23.3 – 27.5 ka; Hughes and Gibbard, 2015) has important implications for the dynamics of terrestrial ice masses and, in particular, proximal mountain ice caps (Clark et al., 2012). In the Irish Sea Basin, ice caps centred on the mountains of Wales (Hughes et al., 2016), the Lake District (Wilson et al., 2013) and Wicklow, Ireland (Ballantyne et al., 2006) coalesced with the ISIS during the LGM and may have persisted after ISIS retreat. However, while the deglacial chronologies of the Welsh and Lake District ice caps are constrained by ^{10}Be , OSL and ^{14}C ages (Ballantyne et al., 2009; McCarroll et al., 2010; Glasser et al., 2012; Lloyd et al., 2013; Hughes et al., 2016; Smedley et al., 2017b), there is a paucity of geomorphological and geochronological evidence for post-LGM activity in the Wicklow Mountains. ^{10}Be ages from summits in Wicklow (Ballantyne et al., 2006) and the adjacent Blackstairs Mountains (Ballantyne and Stone, 2015) indicate summit deglaciation soon after the LGM ($n = 5$; 21.0 – 22.9 ka), while a single ^{36}Cl age from the Mottee Stone (~20 km SE of Lugnaquilla (925m) at 52.886993, -6.208196) indicates separation of mainland ice and the ISIS by 23.1 ± 2.2 ka (Bowen et al., 2002). This timeframe accords with Bayesian modelling of ice stream retreat, with the ISIS retreating ~80 km along the Irish coast during the interval 20.8 – 23.9 ka (Smedley et al., 2017b). Recent research has begun to establish the geomorphological context for deglaciation in the Wicklow Mountains (Knight et al., 2017). However with the exception of isolated ^{14}C ($n = 2$, 11.5 – 11.6 ka; Colhoun and Synge, 1980) and ^{36}Cl ages ($n = 1$; 17.9 ± 1.0 ka; Bowen et al., 2002) from Lough Nahanagan, the geochronology of the deglaciation of the Wicklow Ice Cap is poorly understood. To address this knowledge gap, this study presents 170 Schmidt Hammer (SH) exposure ages from cirque and valley moraines and from a summit overridden by ice at the LGM. These data provide new insights into the contrasting deglacial chronologies of the ISIS and the Wicklow Ice Cap and the climatic and topographic factors which conditioned post-LGM retreat.

Methods

1
2
3 To develop a deglacial chronology, sampling was focused on prominent moraines and
4 boulder accumulations as these are the best geomorphological indicators of the dimensions
5 of former mountain glaciers (Barr et al., 2017). Key sites along the main SW-NE axis of the
6 mountain range were targeted for Schmidt Hammer exposure dating (SHED; Tomkins et al.,
7 2016) including glacially-deposited boulders on prominent cirque moraines (>400 m) at
8 Kelly's Lough, Lough Nahanagan, Mullaghcleevaun and Upper Lough Bray. These moraines
9 exhibit good spatial coherence (Kirkbride and Winkler, 2012) as they are generally matrix-
10 poor, boulder-rich and feature clearly defined moraine crests, although the outer cirque
11 moraine at Lough Nahanagan is degraded (Colhoun and Synge, 1980). This moraine is ~1 km
12 in length, broadly convex in cross-profile form and consists of unsorted granite, sand and
13 gravel deposits with entrained glacially smoothed granite boulders (1 - 4 m diameter;
14 Colhoun and Synge, 1980). Multiple nested moraines and boulder accumulations are
15 preserved within the inferred YD glacial limit at each site, which conforms to a pattern of
16 active oscillatory retreat (Bickerdike et al., 2017). In addition, samples were obtained from
17 valley moraines (250 – 400 m, c. 2 - 4 km from cirque headwalls) at Carrawaystick Brook,
18 Upper Glendasan, Lough Brook and Glenmacnass Waterfall and from ice-moulded bedrock
19 and erratic boulders from the summit of Carrigshouk (571 m), which was overridden by ice at
20 the LGM (Fig. 1; Table 1). 20 surfaces were sampled at each site (Carrawaystick Brook; n = 10)
21 and 170 surfaces were sampled in total, comparable to previous applications of SHED in the
22 Mourne Mountains, Northern Ireland (Barr et al., 2017).

23
24
25
26
27
28
29
30 30 R-values were generated per surface (Niedzielski et al., 2009). Sampled boulders were of
31 sufficient size (> 25 kg; Sumner and Nel, 2002; Demirdag et al., 2009) and all sampled
32 surfaces were free of surface discontinuities (Williams and Robinson, 1983) and lichen
33 (Matthews and Owen, 2008). *Instrument calibration* (Correction Factor = 1.017) and *age*
34 *calibration* (Correction Factor = 0.992) were performed using the SHED-Earth online
35 calculator (<http://shed.earth>) following the recommendations of Dortch et al. (2016). SH
36 exposure ages and 1σ uncertainties were calculated based on the arithmetic mean for each
37 surface (Mean of 30 R-values) and based on the updated calibration curve of Tomkins et al.
38 (2017) which includes ^{10}Be dated surfaces from Blackstairs Mountain, Wexford (n = 2;
39 Ballantyne and Stone, 2015) and Bloody Foreland, Donegal (n = 6; Ballantyne et al., 2007;
40 Clark et al., 2009). These data fit the trend established at calibration sites in Scotland and NW
41 England and indicate that errors in SH exposure age estimates due to climatic variability
42 appear unlikely (Barr et al., 2017). Calibration site exposure ages are calculated using the
43 online calculators formerly known as the CRONUS-Earth online calculator
44 (<http://hess.ess.washington.edu/math/>, Wrapper script 2.3, Main calculator 2.1, constants 2.3,
45 muons 1.1; Balco et al., 2008) and are based on the time-dependent L_m scaling (Lal, 1991;
46 Stone, 2000), the Loch Lomond Production Rate (LLPR; Fabel et al., 2012; 4.02 ± 0.18 atoms
47 $\text{g}^{-1} \text{a}^{-1}$) and assuming 0 mm ka^{-1} erosion. The LLPR is constrained by independent ^{14}C ages
48 (MacLeod et al., 2011) and is the most widely used local production rate in the British Isles.
49 However, the results presented here will be subject to recalibration in light of future
50 refinement of local production rates. For each sampled site (n = 9), probability density

2
3 estimates (PDEs) were produced and modelled to separate out the highest probability
4 Gaussian (Fig. 2; Dortch et al., 2013) to account for geological uncertainty. This analytical
5 method has been employed in studies using ^{10}Be (Dortch et al., 2013; Murari et al., 2014) to
6 identify ages that are too young (*moraine degradation*; Heyman et al., 2011) or too old
7 (*inheritance*; Hallet and Putknonen, 1994).
8
9

10 Based on the results of SHED, three dimensional reconstructions of cirque glaciers were
11 generated using the GLaRe tool (Pellitero et al., 2016; Basal shear stress = 100 kPa; Step
12 length = 10 m) and used to estimate palaeo equilibrium-line altitudes (ELAs). Valley glaciers
13 were also reconstructed for individual catchments using this method although ELAs were not
14 calculated for these ice configurations as geochronological data are not available for all
15 glacier outlets. ELAs were estimated using the GIS tool of Pellitero et al. (2015), applying the
16 area-altitude balance ratio method (AABR = 1.9 ± 0.81 ; Rea, 2009). ELAs are controlled by
17 climate (Ohmura et al., 1992; Hughes and Braithwaite, 2008) but are also strongly influenced
18 by non-climatic factors (Table 2), such as the supply of snow and ice from indirect sources
19 (Mitchell, 1996; Kern and Laszlo, 2010). To assess the impact of 'redistributed' snow and ice,
20 combined snow and avalanche contributing areas (A_c) were calculated (c.f. Ballantyne,
21 2007a,b; Barr et al., 2017; Dominant wind direction W/SW = 210 - 300°, Avalanche slopes \geq
22 25°) and compared to total glacier surface areas (A_g). The A_c/A_g ratio is a proxy for the
23 potential contribution of redistributed snow to glacier accumulation.

32 Results

33
34 Gaussian SH exposure ages (Table 1) are in correct stratigraphic order in individual glacier
35 catchments, are broadly consistent with comparable deglacial chronologies across the British
36 Isles (Clark et al., 2012), and clearly differentiate cirque and valley moraines, with deposition
37 during the Younger Dryas (YD; 11.7 - 12.9 ka) and Oldest Dryas respectively (GS-2.1a; 14.7 -
38 17.5 ka). Moreover, these datasets are chronologically robust (Kirkbride and Winkler, 2012),
39 with well-dated moraine sequences in Glenmalur, Glendasan and Glenmacnass (Fig. 1), and
40 provide a framework for a wider morphostratigraphic deglacial chronology for the Wicklow
41 Mountains (Knight et al., 2017). At cirque sites, SHED indicates deglaciation by 12.31 ± 0.51
42 ka at Upper Lough Bray (ULB), 12.00 ± 0.44 ka at Kelly's Lough (KL), 11.40 ± 0.13 ka at
43 Mullaghcleevaun (MC) and 10.93 ± 0.26 ka for the outer moraine at Lough Nahanagan (LN;
44 Colhoun and Synge, 1980). In contrast, valley moraines were deposited at 16.46 ± 0.58 ka at
45 Glenmacnass Waterfall (GW), 16.21 ± 0.60 ka at Upper Glendasan, 15.48 ± 0.35 ka at
46 Carrawaystick Brook (CB) and 15.41 ± 0.30 ka at Lough Brook (LB). Finally, SHED indicates the
47 emergence of Carrigshouk (CS) by 16.64 ± 0.82 ka. This date provides a minimum age for
48 wider summit deglaciation in the Wicklows Mountains due to its comparatively low elevation
49 (571 m) and central position on the range divide. Reconstructed cirque glaciers (Table 2)
50 range in size from 0.35 km^2 (ULB) to 1.10 km^2 (LN) while snow contributing areas (A_c) range
51
52
53
54
55
56
57
58
59
60

1
2
3 from 0.12 km² (ULB) to 1.07 km² (LN). At Lough Nahanagan and Mullaghcleevaun, extensive
4 upland plateaus to the west and south (210 - 300°) account for large snow contributing areas
5 ($A_c \geq 1$ km²). In contrast, restricted upslope areas within the glacier drainage basin likely
6 limited the potential for significant snow redistribution ($A_c \leq 0.5$ km²) at Kelly's Lough and
7 Upper Lough Bray. AABR ELAs for cirque glaciers range from 513 m (LN) to 648 m (KL) and
8 show no clear spatial clustering. Finally, reconstructed valley glaciers range in size from 4.96
9 km² (UGD) to 12.46 km² (GW) and demonstrate a progressive reduction in total glacier area
10 (A_g) throughout the period 15.4 - 16.5 ka.

16 Discussion

17
18
19 Firstly, these data demonstrate that significant ice masses persisted in the Wicklows after
20 retreat of the ISIS, with large valley glaciers (Length: ~4 km, Area: ~12.5 km²) present until
21 the onset of the Late-glacial (Greenland Interstadial-1; Rasmussen et al., 2014). While lowland
22 (23.1 ± 2.2 ka; Bowen et al., 2002) and summit deglaciation ($n = 3$; 21.0 – 21.9 ka; Ballantyne
23 et al., 2006) was coeval with ISIS retreat (Smedley et al., 2017b), SH exposure ages from the
24 summit of Carrigshouk (571 m) indicate that summit ice fields were present on the range
25 divide until 16.64 ± 0.82 ka. However, distal summits were ice free as early as 21.9 ± 1.1 ka
26 (Djouce Mountain, 725 m), 21.2 ± 1.1 ka (Scarr, 641 m) and 21.0 ± 1.1 ka (Kanturk, 523 m)
27 and evidence a significant time lag in summit deglaciation (~4.4 ka). Collectively, ¹⁰Be and
28 SHED ages indicate rapid downwastage of the Wicklow Ice Cap soon after the LGM and a
29 transition to summit ice fields which sourced discrete outlet glaciers (e.g. Glenmacnass,
30 Glendasan, Glenmalur; Fig. 1). This chronology is consistent with ¹⁰Be ages from summits in
31 Wales (Glasser et al., 2012; Hughes et al., 2016), which record downwastage of the Welsh Ice
32 Cap at 19 - 20 ka (≤ 600 m), while ¹⁴C ages from proximal Welsh lowlands (15.82 ± 0.39 cal.
33 ka BP; Lowe, 1981; Reimer et al., 2013), show that Alpine-style valley glaciers were present for
34 ~4 ka after initial summit emergence (Hughes et al., 2016). These data also accord with a ³⁶Cl
35 age from ice-sculpted bedrock in the Scafell massif, which indicates substantial downwastage
36 of the Lake District ice cap by 17.3 ± 1.1 ka (< 750 m; Ballantyne et al., 2009). Deglaciation of
37 Carrigshouk at ~16.6 ka marks a shift to topographically confined ice flow, with glaciers
38 sourced from high elevation cirques, and likely reflects a time-progressive response to
39 reduced moisture availability and winter aridity during this interval (Kelly et al., 2010).
40 However, these data indicate that summit ice fields and large valley glaciers persisted in the
41 Wicklows for 4 - 7 ka after ISIS retreat (Smedley et al., 2017b), and reveal similarities in the
42 post-LGM histories of the Wicklow, Welsh (Hughes et al., 2016) and Lake District ice caps
43 (Ballantyne et al., 2009). These data accord with wider evidence for post-LGM disintegration
44 of the BIIS into component ice caps (Clark et al., 2012).
45
46
47
48
49
50
51
52

53
54 Secondly, the geomorphological record indicates that post-LGM retreat was dynamic, with
55 valley and cirque re-advance moraines deposited during the Oldest Dryas and Younger
56
57
58
59
60

1
2
3 Dryas respectively (Fig. 2A). Re-advance of valley glaciers during the interval 15.4 - 16.5 ka
4 was coeval with peak ice rafted debris flux (Bard et al., 2000; Eynaud et al., 2009) and reduced
5 sea surface temperatures (Bard et al., 2000) during Heinrich Stadial 1 (Fig. 2B; HS1) and the
6 re-advance of the Irish Ice Sheet (IIS) and the ISIS during the Killard Point Stadial (~16 - 17.1
7 ka; McCabe et al., 2007; Clark et al., 2012). The re-advance of glaciers in Ireland during the
8 Oldest Dryas was matched further down the North-East Atlantic margin in Spain (Palacios et
9 al., 2017). These re-advances are linked to North Atlantic climate perturbations (HS1) and
10 likely reflect short-term oscillations of the ice front (≤ 1 ka) during the long-term post-LGM
11 retreat phase (~8 ka). Moreover, these chronological data match recent morphostratigraphic
12 assessments which support a widespread pattern of sustained retreat interrupted by minor
13 glacier readvance (Knight et al., 2017). Retreat from re-advance positions, estimated at 1.82
14 km ka^{-1} for the Glenmacnass glacier, was synchronous across the Wicklow Mountains, as
15 demonstrated by progressive deglaciation from low to high elevation (Fig. 3A; $R^2 = 0.9116$; p
16 $= 0.045$). These data are indicative of climate-controlled retreat with independent outlet
17 glaciers responding synchronously to reduced moisture availability (Kelly et al., 2010),
18 irrespective of contrasting glacier aspects, source areas or glacier extents. Oldest Dryas valley
19 glaciers were extensive ($\leq 12.5 \text{ km}^2$), sustained by ice fields and prior to ~16.6 ka,
20 overtopped low-lying summits (~571 m). As a result, the potential for significant
21 redistribution of snow and avalanche material ($A_c > A_g$) was limited, particularly during
22 periods of winter aridity (Kelly et al., 2010). Therefore, while topography likely influenced the
23 retreat pattern in individual valleys, post-LGM retreat (~15 - 17 ka) was primarily paced by
24 climate.

25
26
27
28
29
30
31
32
33 In contrast, marked asynchronicity in the timing of final YD deglaciation (Fig. 3; 11.4 - 12.3 ka)
34 is unrelated to cirque elevation (Fig. 3A; $R^2 < 0.01$, $p = 0.97$), palaeo-ELA (Fig. 3E; $R^2 = 0.04$, p
35 $= 0.81$) or site latitude ($R^2 = 0.10$, $p = 0.69$). These data suggest that climate was not the
36 dominant control on the timing of final YD deglaciation. Instead, glacier retreat was strongly
37 controlled by local topography and the redistribution of wind-blown snow and avalanche
38 material (Fig. 3B; $R^2 > 0.99$, $p < 0.01$). Combined snow and avalanche contributing areas (A_c)
39 range from just 0.119 km^2 at Upper Lough Bray to 1.071 km^2 at Lough Nahanagan. For
40 glaciers with large A_c areas, topography may exert the primary control on glacier formation
41 and survival, and may account for the comparatively late-deglaciation of Lough Nahanagan
42 and Mullaghcleevaun during the early-Holocene. By comparison, glaciers with small A_c areas,
43 where the potential for redistribution of snow and avalanche material is limited, may respond
44 quasi-synchronously to climate warming. For example, the early deglaciation of Upper Lough
45 Bray at 12.31 ± 0.51 ka is coeval with a gradual rise in summer air temperatures after ~12.5
46 ka (Brooks and Birks, 2000) which was likely sufficient to raise the 'climatic' ELA above cirque
47 elevations ($A_c/A_g = 0$; Barr et al., 2017) and initiate mass wastage. In contrast, abundant snow
48 redistribution ($A_c \geq 1$), conditioned by existing topographic configurations (extensive upland
49 plateaus), was likely sufficient to locally suppress the 'local' (non-climatic) ELA and promote
50 glacier survival at other sites. However, the contribution of redistributed snow to glacier
51 accumulation almost certainly diminished throughout the YD as summer air temperatures
52
53
54
55
56
57
58
59
60

1
2
3 increased rapidly towards the onset of the Holocene (Brooks and Birks, 2000), thus limiting
4 snowpack preservation. These data indicate that while regional climate provides the baseline
5 conditions for glacier growth and decay, cirque glacier dynamics may primarily reflect the
6 influence of topography. However, there is a weak correlation between glacier size (A_g) and
7 deglaciation age (Fig. 3C; $R^2 = 0.77$, $p = 0.12$), although the size variation between the
8 smallest (ULB; 0.35 km^2) and largest reconstructed glacier (LN: 1.10 km^2) is minimal (~ 0.75
9 km^2). As such, significant within-mountain range variation in glacier response times is not
10 anticipated (Raper and Braithwaite, 2009). This may account for the weak correlation
11 between A_c/A_g ratios and deglaciation ages (Fig. 3D; $R^2 = 0.58$, $p = 0.24$) although the
12 observable trend demonstrates the probability of early deglaciation for glaciers with small
13 A_c/A_g ratios. Based on this reasoning, we conclude that for small YD glaciers, local
14 topoclimatic controls can be more significant than wider regional climate in determining
15 cirque glacier dynamics, and in particular, the timing of final deglaciation. This result has
16 important implications for palaeoclimate reconstructions based on dating of cirque moraines
17 (e.g. using ^{10}Be), as cirque glacier ELAs are not representative of the regional climate and
18 consequently glaciers dynamics are likely to be decoupled from climatic changes occurring
19 in the North Atlantic region. This phenomenon is observed today in the behaviour of small
20 glaciers in marginal glaciated settings such as the Italian Alps (Colucci, 2016) and other
21 Mediterranean mountains (Hughes, 2018). These data from Ireland also show that the impact
22 of topography on glacier dynamics is most significant when glaciers are small ($\leq 1 \text{ km}^2$),
23 resulting in clear asynchronicity in deglaciation (Fig. 3A; $R^2 = < 0.01$), and provide further
24 evidence that the climatic integrity of cirque glaciers may be limited (Kirkbride and Winkler,
25 2012). In contrast, large glaciers ($\sim 12.5 \text{ km}^2$), with limited potential for snow redistribution,
26 have been shown to respond synchronously to climate forcing (Fig. 3A; $R^2 = 0.9116$).
27 Modelling studies have shown that topoclimatic variables (solar radiation/snow
28 redistribution) can predict the style of deglaciation (moraine distribution) for small Younger
29 Dryas glaciers (Coleman et al., 2009; Bickerdike et al., 2017). The chronological data
30 presented here provides new evidence that topographic controls not only influence the style
31 of deglaciation, but can determine the timing of final deglaciation, with clear within-
32 mountain range variability.

33
34
35
36
37
38
39
40
41
42
43 A further challenge in linking cirque glacier dynamics to climatic fluctuations is the potential
44 impact of moraine stabilisation (Hallet and Putknonen, 1994). This post-depositional process
45 can result in moraine ages (e.g. ^{10}Be) which post-date glacial retreat. A 1-2 ka early
46 stabilization period has been recorded for Alpine moraine sequences in Alaska and the Alps
47 (Briner et al., 2005; Ivy-Ochs et al., 2006, 2008; Dortch et al., 2010a). In these environments,
48 glaciers can produce distinctive asymmetric ice-contact fans that undergo rapid gullyng and
49 post-depositional reworking on their ice-proximal slopes (e.g. Hambrey et al., 2012; Lukas et
50 al., 2012). However, these landforms are topographically and sedimentologically distinct from
51 the low-relief, topographically concordant valley and cirque landsystems found in the
52 Wicklow Mountains. Moreover, there has been comparatively little attention to processes of
53 moraine development and deglaciation dynamics in these environments, with analogue
54
55
56
57
58
59
60

1
2
3 studies predominantly focused on 'hummocky moraine' landsystems (e.g. Benn and Lukas,
4 2006), and a relative paucity of research into moraine processes in smaller cirque type
5 landsystems, likely under the assumption of rapid stabilisation after deglaciation. Recent
6 work has highlighted the importance of self-censoring in cirque environments due to
7 oblitative overlap (Barr and Lovell, 2014) or ice-cored moraine degradation (Crump et al.,
8 2017; Tonkin et al., 2017), while external-censoring due to slope instability may also provide
9 a control on moraine stabilisation (Barr and Lovell, 2014). As a result, there is considerable
10 uncertainty regarding the robustness of chronological datasets for cirque moraine systems
11 (Kirkbride and Winkler, 2012). To produce better-resolved glacier chronologies, researchers
12 can account for moraine stabilisation through (1) morphostratigraphic comparison of
13 moraine sequences, (2) Gaussian separation of exposure ages (Dortch et al., 2013), (3)
14 assessment against independent geochronological data (e.g. ^{14}C , OSL) and (4) consideration
15 of modern process studies and likely modern analogues for moraine assemblages when
16 assessing site suitability for a give geochronological approach (e.g. Çiner et al. 2015). Based
17 on these criteria, we infer that moraine stabilisation may be a key post-depositional process
18 for the outer moraine at Lough Nahanagan. Firstly, this moraine is degraded (Colhoun and
19 Synge, 1980) and is morphologically distinct from sampled cirque moraines at
20 Mullaghcleevaun, Kelly's Lough and Upper Lough Bray which are tall (> 3 m), matrix-poor,
21 boulder-rich, and feature clearly defined moraine crests (Fig. 4). Secondly, Gaussian
22 separation of SHED data for this site ($n = 20$) reveals a clear 'two-peak' probability density
23 function (Fig. 2C), with Gaussian ages of 10.93 ± 0.26 ka ($n = 9$) and 11.38 ± 0.26 ka ($n = 9$).
24 The youngest age post-dates the YD by ~ 0.8 ka and is inconsistent with wider evidence for
25 deglaciation of the British Isles by the YD/Holocene transition (MacLeod et al., 2011)
26 although in isolation, this observation is insufficient to reject this age at this stage. In
27 addition, this method highlights clear outlier ages ($n = 3$; 12.8 - 13.5 ka). These Gaussian
28 ages can be rejected as they are comprised of fewer than 3 ages (c.f. Fig. 3 in Dortch et al.,
29 2013). Finally, independent ^{14}C ages indicate deglaciation during the late YD and early
30 Holocene (11.5 - 11.6 ka; Colhoun and Synge, 1980). In contrast, a single ^{36}Cl age suggests
31 ice free conditions since 17.9 ± 1.0 ka (Bowen et al., 2002), although this age likely reflects
32 prior exposure (*inheritance*) and is rejected from further analysis. Based on these data, we
33 conclude that the older Gaussian age of 11.38 ± 0.26 ka is more representative of final
34 deglaciation as this age is consistent with previous ^{14}C ages and accounts for both the
35 distinctive geomorphological assemblage at this site and the clear 'two-peak' distribution of
36 SHED ages. This conclusion indicates that moraine stabilisation and boulder exhumation may
37 account for the degraded moraine surface and comparatively 'young' SHED ages. These data
38 provide further evidence that moraine ages are more likely influenced by post-glacial
39 instability than prior exposure (Shanahan & Zreda 2000; Putkonen & Swanson 2003; Zech et
40 al. 2005; Heyman et al. 2011; Applegate et al., 2012). As a result, the dynamics of small cirque
41 glaciers (< 1 km²), as determined by radiometric methods (^{10}Be), may not only primarily
42 reflect topographic controls, but may be profoundly influenced by post-depositional
43 processes. The post-depositional evolution of YD moraine systems is largely unexplored at

3 present and a clear co-benefit of the SHED approach is the potential insight into these
4 processes; insight that was not afforded by other geochronological approaches. Future
5 research should carefully consider landform context (Barr and Lovell, 2014) and prioritise
6 sampling of cirque environments where snow and avalanche contributing areas (A_c) are small
7 (Warren, 1991; Mills et al., 2012; Barr and Lovell, 2014), where postglacial erosion is limited
8 and where short transport distances promote the formation of matrix-poor boulder-rich
9 moraines (Fig. 5; Pallàs et al., 2010). In these environments, snow redistribution is limited and
10 moraines are more likely to stabilise rapidly after deglaciation. As such, these glaciers may
11 respond quasi-synchronously to climatic fluctuations and may produce more robust
12 palaeoclimatic reconstructions.

19 Conclusions

20
21 This study provides the first chronological constraints on post-LGM retreat of the Wicklow
22 Ice Cap. 170 SH exposure ages from cirque and valley moraines and from a summit
23 overridden by ice at the LGM demonstrate that significant ice masses persisted in the
24 Wicklows after retreat of the ISIS and were sustained by summit ice-fields until ~16.6 ka.
25 Post-LGM retreat was dynamic, with re-advance moraines deposited during the Oldest Dryas
26 in response to HS1 cooling. However, these events reflect short-term oscillations (≤ 1 ka) of
27 the ice front during the long-term retreat phase (~8 ka), which was driven by reduced
28 moisture availability and winter aridity. This chronology is matched by ^{10}Be and ^{14}C ages from
29 the Welsh Ice Cap, with downwastage during the interval 19-20 ka, while alpine valley
30 glaciers persisted for ~4 ka after initial summit emergence. Retreat from re-advance
31 positions was paced by climate, with time-progressive deglaciation from low to high
32 elevation ($R^2 = 0.9116$). In contrast, asynchronicity in final Younger Dryas deglaciation is
33 accounted for by local topography and the redistribution of snow and avalanche material.
34 Contrasting synchronicity in the timing of glacial retreat during these periods is conditioned
35 by glacier size, with small YD glaciers ($< 1 \text{ km}^2$) highly sensitive to local topographic controls.
36 This result has important implications for palaeoclimate reconstructions based on dating of
37 cirque moraines (e.g. ^{10}Be), as cirque glacier dynamics may be unrelated to climate. This is
38 further complicated by post-depositional processes which can result in ages which post-date
39 retreat. As a result, future palaeoclimate reconstructions should prioritise cirque glaciers
40 where snow and avalanche contributing areas (A_c) are small and where the potential for
41 post-depositional disturbance is limited (matrix-poor, boulder rich moraines).

52
53 Figure 2. Gaussian ages related to deglaciation of the Wicklow Mountains. A: The NGRIP
54 Oxygen Isotope Curve (Rasmussen et al., 2014) plotted against 1σ age boundaries for
55 sampled cirque and valley sites. The Younger Dryas (YD) and Oldest Dryas (OD) periods are
56
57
58
59

1
2
3 marked. B: Ice rafted debris and sea surface temperature records from cores SUBI-18 (Bard et
4 al., 2000) and MD95-2039 (Eynaud et al., 2009) in the North Atlantic. C: Gaussian models for
5 sampled cirque and valley sites. For each site, the highest probability Gaussian is considered
6 the most likely timing of deglaciation as all ages are younger than the Last Glacial Maximum
7 (Dortch et al., 2013). At Lough Nahanagan, the oldest peak with more than 3 ages is selected
8 (c.f. Dortch et al., 2013) as this moraine is degraded and morphologically distinct from other
9 sampled cirque moraines (MC, KL, ULB). Moreover, this estimates matches previous ^{14}C ages
10 (Colhoun and Synge, 1980).
11
12
13

14 Figure 3. Topographic and climatic controls on the timing of cirque deglaciation in the
15 Wicklow Mountains. A: Site Elevation; B: Snow contributing area (A_c); C: Glacier area (A_g); D:
16 A_c/A_g ratio; E: ELA; F: ELAs and A_c/A_g ratio plots. These data show that for large valley glaciers,
17 retreat is paced by climate with progressive deglaciation from low to high elevation (A). In
18 contrast, marked asynchronicity in the timing of cirque deglaciation (A) is strongly controlled
19 by snow redistribution (B). This asynchronicity is weakly correlated with glacier size (C) and
20 A_c/A_g ratios (D) and is unrelated to ELA (E).
21
22
23

24 Figure 4. Sampled cirque moraines at Lough Nahanagan (A), Mullaghcleevaun (B), Kelly's
25 Lough (C) and Upper Lough Bray (D). The outer cirque moraine at Lough Nahanagan is
26 degraded (Colhoun and Synge, 1980) and is morphologically distinct from other cirque
27 moraines which are sharp crested, boulder-rich and matrix-poor.
28
29

30 Figure 5. Matrix-poor, boulder-rich moraine at Mullaghcleevaun which likely stabilised
31 rapidly after deglaciation.
