Abstract—The cognitive network uses cognitive processes to record data transmission rate among nodes and applies self-learning methods to trace data load points for finding optimal transmission path in the distributed computing environment. Several industrial systems, e.g., data-centers, smart grids, etc., have adopted this cognitive paradigm and retrieved the least HOP count paths for processing huge datasets with minimum resource consumption. Therefore, this technique works well in transmitting structured data such as ‘XML’, however, if the data is in unstructured format i.e. ‘RDF’, the transmission technique wraps it with the same layout of payload and eventually returns inaccuracy in calculating traces of data load points due to the abnormal payload layout. In this paper, we propose a knowledge-based optimal routing path analyzer (RORP) that resolves the transmission wrapping issue of the payload by introducing a novel RDF-aware payload-layout. The proposed analyzer uses the enhanced payload layout to transmit unstructured RDF triples with an append pheromone (footsteps) value through cognitive nodes towards the semantic reservoir. The grid performs analytics and returns least HOP count path for processing huge RDF datasets in the cognitive network. The simulation results show that the proposed approach effectively returns the least HOP count path, enhances network performance by minimizing the resource consumption at each of the cognitive nodes and reduces traffic congestion through knowledge-based HOP count analytics technique in the cognitive environment of the smart grid.

Index Terms—Cognitive network, Semantic dataset, Apache Hadoop, RDF Triple, Ant colony optimization, Smart grid.

I. INTRODUCTION

A cognitive network is a data communication paradigm that facilitates nodes with runtime on-demand service processing in the distributed computing environment [1]. It’s network infrastructure consists of cognitive processes that invoke operations to perform runtime tasks such as record, monitor, append data before it reaches final destination node. Because of these custom feature to fulfill on demand requirements, several organizations adopt cognitive network framework for data processing i.e., IT data-centers and smart grid [2].

A smart grid is a self-driven power generation and distribution system that widely adopts cognitive network features and applies to the infrastructure through three-tier architecture [3]. The first-tier consists of edge nodes that perform sensory operations and generate sensor information dataset. The second-tier transforms these datasets into Resource Description Framework (RDF) triples workloads and transmit them through various transmission paths of cognitive network towards semantic repository. The third-tier performs various types of data analytics for maintaining, monitoring and processing activities of smart grid [4] as shown in Fig. 1.

In this way, we observe that the smart grid assess the transmission rate and the distance between network nodes through cognitive processes and draw a routing path to deliver RDF triple towards semantic reservoir [5], [6]. Therefore, the grid finds individual data transmission rate of a node NodeTR = \sum_{\text{Data}} \frac{\text{Bandwidth}}{\text{Packet}_i} and the overall grid GridTR = \sum_{\text{Dataset\ RDFTriple}} \frac{\text{Bandwidth}}{\text{Packet}_i} in its cognitive network [7].

These transmissions calculate RDF processing path with HOP count and deliver triples in the semantic reservoir. In this way, we observe that the delivery path only emphasizes on working of cognitive processes and traditional network path optimization strategies to transmit RDF triples. This increases uncertain complexity between cognitive network functionality and measurement of path HOP count and results in a non-compliance among functions in the form of network congestion FlowNode(i) = (\text{TripleChunk}_{k-1} \otimes \text{TripleChunk}_{k-2}) [8]. Moreover, it maximizes network overflow issues and deactivates nearest node search function to transmit RDF triples using Euclidean distance \text{Di} = \sqrt{\sum_{j} (x_j - x_i)^2} [9]. Thus,

grid consumes time latency to locate an alternate of related cognitive nodes and smart grid performs poor in transmitting semantic data towards its reservoir as shown in Fig. 2.

To resolve this issues, we propose RDF-aware optimal routing path strategy (RORP) that analyzes all the transmission paths and extracts least HOP count path through ant colony pheromone technique to transmit RDF dataset into a semantic reservoir. The main contributions of this paper are highlighted as:

- A novel enhancement of payload data segment structure to fix RDF triples.
- A modified cognitive process that reads RDF workload concurrently using customized payload structure.
- Insertion of pheromone value into RDF triple payload.
- Pheromone-aware RDF dataset storage into semantic reservoir.
- A novel knowledge-based RDF data transmission strategy that reduces network congestion and maintains nodes intact to process dataset with least HOP count in the smart grid.

The remaining paper is organized in the following manner. Section II motives the modern technology requirements to adopt ant colony optimization approach for obtaining least HOP count in cognitive network. Section III briefly elaborates RDF-aware optimal routing path strategy (RORP). Section IV presents the performance evaluation of RORP individually and with comparative analysis over designed Apache Hadoop cluster. Section V concludes the proposed approach RORP with recommendations of future works.

II. MOTIVATION

Finding optimal routing path with least HOP count in a large-scale cognitive network such as smart grid is no less than a challenge in today’s distributed computing environment. There are several schemes and routing protocols that focus to address this issue by effective gradient data transmission schemes [10], adaptive HOP routing protocols [11], robust diffusion algorithms using ant colony optimization [12] and energy-efficient diffusion routing algorithms [13], however, no of them resolves this problem through knowledge-based analytics. To the best of our knowledge, RORP is first of its kind that addresses optimal routing path issue through calculating load onto cognitive network nodes and append load value as pheromone on its RDF-enabled data payload. The semantic reservoir stores this RDF payload and performs analytics over large-scale repository that highlights information related to all the routing paths of smart grid with minute processing details that helps finding optimal path having least HOP count through data analytics.

III. RDF-AWARE OPTIMAL ROUTING PATH (RORP)

The proposed approach (RORP) finds least HOP count path of processing RDF triples in the cognitive network of smart grid. This strategy consists of five steps i.e., A) RDF triple payload, B) knowledge-based cognitive processing, C) append pheromone onto triple payloads, D) pheromone-aware RDF reservoir and E) Knowledge-based optimal routing path analyzer.

RORP uses these steps in such a hierarchical way that, at first, a simple message payload is transformed into RDF triple compatible payload. In the next step, it calculates the individual load on each of the triple payloads using RDF-aware cognitive process. After that, a pheromone value is appended onto every triple payload and those pheromone-aware payloads are stored in a semantic reservoir. In the last, the optimal routing path analytics evaluate the minimum HOP count used path in the cognitive network of a smart grid.

A. Step-1: RDF Triple Payload

The payload is a data part of RDF triple transmitted onto the cognitive network of smart grid. By default, the structure of triple payload consists of a single data block that stores subject, predicate and object information in a single capsule [14] and can be expressed as,

$$RDF_{Packet} = (Header_{Length}, Payload_{Length})$$  \hfill (1)

RORP enhances this payload packet message into three parts such as sub-payload, pred-payload and obj-payload with individual header id assigned to each of them. Therefore, when a cognitive process performs a network operation, RDF triple returns individual part data transmission rate along with its execution time-stamp. The categorized payload packet is expressed through Fig. 3 and can be obtained as,

$$RORP_{RDF(Packet)} = \{(H_{Sub}, P_{Sub}), (H_{Pred}, P_{Pred}), (H_{Obj}, P_{Obj})\}$$  \hfill (2)
calculated as,

\[ \text{Load}_{\text{Node}} = \frac{\sum \text{Load}_{\text{CP}_i}}{\text{CP} (\text{Memory}, \text{CPU}, \text{1/0})} \]  

C. Step-3: Append Pheromone onto Triple Payloads

The term ‘phermone’ represents a footstep value used to memorize the workload on a network path. In case of a cognitive network, we use cognitive process value \( \text{Load}_{\text{CP}_i} \) as a phermone that keeps track of previous individual RDF triple processing on a particular node. The phermone between two cognitive nodes can be expressed as,

\[ P_{\text{Node}(i,j)} = \frac{\text{Load}_{\text{CP}_i}}{\text{Load}_{\text{Node}(i,j)}} \]  

Where, ‘\( \tau \)’ is the amount of phermone and ‘\( P \)’ depicts the obtained value of phermone in the reservoir of cognitive network. In order to get a complete perspective of phermone between two nodes, RORP updates it with recent \( \text{Load}_{\text{CP}_i} \) values as,

\[ \tau_{i,j} = (1 - p) \tau_{i,j} + \Delta \tau_{i,j} \]  

Where, ‘\( p \)’ is the rate of phermone evaporation and ‘\( \Delta \tau_{i,j} \)’ is the phermone deposited into semantic reservoir as,

\[ \Delta \tau_{i,j} = \begin{cases} \frac{1}{\text{Bandwidth}_{\text{RDF}(\text{Sub}, \text{Pred}, \text{Obj})}} & \text{if } \text{RORP}_{\text{RDF}} = \text{node}_{(i,j)} \\ 0 & \text{otherwise} \end{cases} \]  

In order to receive phermone statistics of all the nodes of cognitive network, RORP updates it with recent \( \text{Load}_{\text{Node}} \) values as,

\[ \tau_{i,j} \leftarrow (1 - p) \tau_{i,j} + \sum_{k=1}^{m} \Delta \tau_{i,j} \]  

Where, \( m \) is the number of nodes and \( \Delta \tau_{i,j} \) is the phermone value over the cognitive network as,

\[ \Delta \tau_{i,j} = \begin{cases} \frac{1}{\text{Bandwidth}_{\text{Node}_{(i,j)}}} & \text{if } \text{RORP}_{\text{RDF}} = \text{node}_{(i,j)} \\ 0 & \text{otherwise} \end{cases} \]  

D. Step-4: Pheromone-aware RDF Reservoir

The phermone-aware RDF reservoir contains a computational environment that includes node table, triple indexes, prefix table and in-line values. The node table manages RORP triple datasets \( \tau_{\text{Load}_{i,j}} \) with a customized concatnation declaration of phermone value with triple payload \( \text{RORP}_{\text{RDF}(\text{Packet})} \). The triple indexes consists of two-dimensional double array accessibility feature that fetches the triple payload with associated phermone values. The prefix table maps phermone-index with large-scale node table index and in-line values wrap phermone and triple data-types together to present a single RDF entity as obtained through stored RORP dataset \( \Delta \tau_{\text{Load}_{\text{Node}}_{i,j}} \).
E. Step-5: Knowledge-based Optimal Routing Path Analyzer

The optimal routing path analytics is a procedure to identify the shortest path having least HOP count to process RDF triples. This is carried out through processing a knowledge-based analyzer over stored $\Delta \tau_{LoadNode_{i,j}}$ pheromone RDF triple dataset on the semantic reservoir of the smart grid as shown in Fig. 5.

Algorithm 1 Optimal Routing Path Analyzer

1: procedure READ SEMANTIC RESERVOIR($\Delta \tau_{LoadNode_{i,j}}$)
2: Scan $RORP_{RDF}(Packet)$
3: Count $P_{Node_{(i,j)}}$
4: while Count $\leq C_{i+j}$ do
5:   Compare $\tau_{LoadCP_{i,j}}$ with Process count
6:   Compare $\tau_{i,j}$ with Node count
7:   Calculate $HOP\left(\tau_{LoadCP_{i,j}}, \tau_{i,j} \right)$ Count
8: return Path

Algorithm-1 presents a systematic retrieval of HOP count through the semantic reservoir pheromone-aware dataset $\Delta \tau_{LoadNode_{i,j}}$ and evaluates least HOP count path of the cognitive network in the smart grid.

IV. EXPERIMENTAL WORK

In order to evaluate RORP, we performed experimental executions over a Hadoop cluster configuration as mentioned in Table-II.

A. Environment

The hardware configuration includes Intel Xeon processor with 8 CPU units, 32GB processing memory and storage media i.e. 128GB Samsung SSD, 1TB disk Seagate Hard Disk Drive, and tmfs utility for RAM_DISK storage processing. Additionally, we have used Intel core i5 processor with 4 Cores, 16GB processing memory and storage media i.e. 128GB Samsung SSD, 500GB Hard Disk Drive, and tmfs utility as RAM_DISK storage processing. The virtual environment includes Virtualbox 5.1.34 over 5 virtual machine configurations as elaborated in Table-III.

B. Experimental Dataset

The dataset used to process experimental work includes:
1) 1 GB CSV (source file) (10 Smart meters unstructured dataset) [16], [17]

C. Experimental Results

The experiments conducted to evaluate RORP are:
1) RDF Triple payload storage,
2) Cognitive process pheromone generation,
3) Pheromone-aware RDF Triple,
4) Cognitive node load analytics, and
5) Comparative analysis.

1) RDF Triple Payload Storage: By default, an RDF triple contains a layout of two structure segments such as header and payload. The header stores prefix and postfix acknowledgment messages that identifies a data packet layout and the payload segment manages subject, predicate and object tuple information [14]. The proposed analyzer RORP redesign this payload segment into three sub-parts such as sub-payload, pred-payload and obj-payload each equivalent of 1 KB to store individual tuple information through ‘PAYLOAD_CAT’ function. Simultaneously, it extracts triples from source dataset and wrap individual tuple data using a wrapper function ‘PAYLOAD_WRAP’ for storing into the already generated sub-payloads segments. This reduces RDF
payload transmission workload evenly on the cognitive nodes and improves the performances of cognitive processes in the smart grid as shown in Fig. 6.

2) Cognitive Process Pheromone Generation: A cognitive process uses TRIPLE_RECORD function to capture RDF triples workload passing through the network nodes. As we know that, the load of a node is measured in terms of memory consumed per RDF triple [2]. Therefore, this load value is labeled with the name of ‘pheromone’ and identified as the workload footsteps at particular interval of time. RORP observes these footsteps with a time-interval of ‘5’ seconds and incorporates them within the new ‘sub-payloads’ of RDF triple. In this way, we observe two individual activities i.e., load processing and pheromone processing. In the load processing, cognitive process records original RDF ‘sub-payload’ sample that consumes computing capacity, memory and I/O of the node, whereas the pheromone processing consumes less computing capacity, memory and I/O of the node compared to load processing because of simply encapsulating pheromone sample to existing RDF ‘sub-payload’ of 100 MB dataset as shown in Fig. 7.

3) Pheromone-aware RDF Triple: Pheromone-aware RDF triple includes the footstep record value along with original sample of RDF. In order to evaluate an actual difference between pheromone-aware and original RDF triple processing, we processed ‘2’ individual datasets i.e., with-pheromone and without-pheromone on a single node ‘slave1’ as discussed in Table-III and observed an additional consumption of node processing percentile in pheromone-aware RDF triple case than original RDF triple as shown in Fig. 8. This extra consumption of node processing percentile will no longer be a disadvantage once Hadoop cluster starts performing analytics on semantic reservoir.

4) Cognitive node load analytics: The cognitive network of smart grid performs various cognitive processes simultaneously to transmit RDF triples through multiple paths [18]. The same is the case of pheromone-aware RDF triple processing onto a cognitive network that also adopts various paths to transmit RDF triples towards semantic reservoir. There can be many reasons for adopting multiple paths such as decreasing the factor of failure in RDF transmission, reducing the assumption of triple corruption and ensuring the storage of exact number of RDF triples into semantic reservoir [19]. These advantages become more useful, when the precise load onto each of the listed path is calculated by means of individual cognitive nodes’ load. We arrange 6 random paths with the help of simulation environment based on ant colony optimization approach and calculates that path ‘A’ consumes least average load percentile than other cognitive network paths as shown in Fig. 9. The reason of such a low load consumption refers to the involvement of lower HOP count number in processing the RDF triples on cognitive network.
Also, the proposed approach adds pheromone onto the RDF that each tuple such as subject, predicate and object can enhance of payload segment into three sub-payloads so that cognitive process can analyze the node workload and evaluate optimal processing path with least HOP count in the smart grid. The evaluation results show that RORP effectively addresses the RDF data transmission and identifies optimal load path with least HOP count in the cognitive network of the smart grid.
