## Abstract

Catalytic converters with non-linear channel structures were prepared using 3D printing and tested in the oxidation of methane in a simulated dual-fuel engine exhaust stream. The design used a simple repeating angular offset between adjacent layers, which was sufficient to introduce complexity with minimal software programming. All 3D printed substrates were mechanically stable and, following washcoating with a composite catalyst, demonstrated higher catalytic activity in methane oxidation than a commercial honeycomb substrate. The methane conversion at e.g. 510 °C was 12.6% on the commercial sample, 72.6% for 90 °, 80.1% for both 30 ° and 45 °, and 89.6 % for the 60 ° oriented structures. This enhancement is attributed to the increased turbulence/mass transfer and surface area than are possible using conventional straight-channelled substrates. Computational fluid dynamics (CFD) analysis confirmed that the higher methane conversion over 3D printed substrates is due (at least partially) to its higher turbulence kinetic energy. Backpressures over the 3D printed structures were also experimentally measured and compared with the conventional honeycomb monolith.

Keywords: dual fuel, methane oxidation, 3D print, additive manufacturing, ceramic, CFD

## 1. Introduction

Diesel engines are preferred for heavy-duty applications such as domestic and commercial transportation due to their durability, fuel efficiency and higher power density. However, these engines greatly contribute to environmental pollution caused by harmful exhaust emissions[1]. The main pollutants from diesel engines are CO, CO<sub>2</sub>, unburnt hydrocarbon, NO<sub>x</sub> and particulate matter (PM) which have an adverse effect on the natural

environment, land, water, air and, therefore, human health[2]. In 2012, the emissions from diesel engine exhaust were classified as carcinogenic to humans by the International Agency for Research on Cancer (IARC), which is part of the World Health Organization (WHO)[3]. Stricter new regulations on exhaust emission and depletion of fossil fuel resources have forced companies to utilise an alternative fuel and/or technology to overcome this problem. Supplementary fuels such as LNG[4], LPG[5], CNG[6], biogas[7], methanol[8], hydrogen[9], and ammonia[10] have been studied in dual fuel diesel engines, in which LNG and CNG have attracted the greatest attention due to their cost-effectiveness and environmental benefits[11]. Natural gas, which contains mostly methane, is a promising alternative fuel for the transportation sector because it is available at a lower price and produces lower carbon emissions. It has the lowest carbon to hydrogen ratio of any hydrocarbon and, therefore, produces less CO<sub>2</sub> and nearly zero smoke or PM, which is almost impossible in diesel-only engines. Moreover, it significantly reduces the NO<sub>x</sub> emission by approximately 50–80%[12]. Other advantages of natural gas include its higher octane number, which means the gas burns hotter and, therefore, can reduce the knocking effect, especially in diesel engines where the compression ratio is relatively high[13]. Furthermore, it has better mixing with air, causing uniform temperature distribution and higher thermal efficiency, which can only be achieved on diesel engines at high loads[14]. However, one of the main drawbacks of using natural gas in dual fuel engines is higher emission of carbon monoxide and unburnt methane from the engine known as “methane slip”. This phenomenon is more dominant at low to medium loads. It has been reported that around 90% of the total hydrocarbons (THC) emissions in a CNG/diesel dual fuel engines are unburned methane[6]. The amount of methane emission on a marine vessel with a LNG/diesel dual fuel engines was reported to be around 7 g.kg<sup>-1</sup> LNG at high load, rising to 23-36 g.kg<sup>-1</sup> LNG at lower loads.

One practical solution to effectively reduce emission content in the exhaust is to use a catalytic converter. Catalytic converters are made of ceramic or metal substrates coated with active catalysts which are widely used in environmental applications such as three-way catalyst (TWC) for CO and hydrocarbon oxidation and selective reduction of NO<sub>x</sub> in small engines; elimination of volatile organic compounds (VOCs) and other organic compounds; hazardous air pollutants (HAPs); and odorous emissions from gaseous effluents[15]. In the auto industry, the common catalyst support for exhaust gas treatment has a monolithic honeycomb structure with a series of parallel tubes and cell density ranging from 300 to 1200 CPSI (cells per square inch). The main reasons that the monolithic honeycomb support is still the first choice for catalyst support in the exhaust after-treatment systems are: available and cost-effective extrusion technology; straightforward

58 washcoating methods; flexibility in cell design; low-pressure drop; and good heat and mass transfer rates [16].

59 Generally, an ideal monolith with high efficiency should have the following criteria: 1) high surface area to

60 volume ratio; 2) high penetrability with low back pressure; 3) high mechanical strength; 4) low thermal

61 expansion; 4) high-temperature shock resistance; 5) corrosion resistance; 6) chemical inertness[17]. However,

62 having all these properties in one package is extremely challenging, and even the best commercial products

63 cannot meet all these criteria.

64 Ceramics are the most frequently used materials for manufacturing monolith. Different ceramic materials such

65 as aluminium titanate ( $\text{Al}_2\text{TiO}_5$ ), calcium titanate ( $\text{CaTiO}_3$ ) and silicon carbide ( $\text{SiC}$ ) have been used[18], yet

66 cordierite, with the chemical composition of  $2\text{MgO} \cdot 2\text{Al}_2\text{O}_3 \cdot 5\text{SiO}_2$ , has become the material of choice owing to

67 its relatively low thermal expansion coefficient and high thermal shock resistance[19].

68 The channel size and structure of the substrate play an important role in the overall performance. The channels

69 of the most common substrates typically have square, circular or triangular shaped cross-sections that extend in

70 one dimension, similar to a honeycomb structure. These channels provide space for the flow of gases and/or

71 liquids that interact with the active catalyst dispersed on the channel walls via washcoating.[20] Figure 1 shows

72 the relation between wall thickness ( $w$ ), repeat distance ( $s$ ), and cell density ( $N$ ) which is defined as channels

73 per unit of cross-sectional area in inches (CPSI). Other parameters such as open frontal area (OFA) and catalyst

74 loading areas (GSA) can be calculated from  $w$  and  $s$ .

Figure 1. Relation between monolith structural parameters.

78 Ceramic substrates with CPSI in the range 25-1200 have been manufactured but the most common range for

79 automotive catalytic converter applications is 400-900 CPSI and 0.004 in (0.1 mm) wall thickness[17]. Ultra-

80 thin wall (UTW) ceramic substrates with 900-1200 CPSI and 0.002 in (0.05 mm) wall thickness have been also

81 manufactured and tested. It has been shown that the UTW substrates provide the possibility of reducing the

82 costs of the exhaust system by reducing the amount of precious metals and/or reducing the catalyst volume.

83 However, these substrates have lower mechanical strength and shorter lifespan due to being more prone to  
84 damage[21].

85 Metallic monolith structures have been manufactured as catalytic converter supports. These substrates can be  
86 made with thinner walls and bigger open frontal areas close to 90%, allowing a lower pressure drop. The material  
87 used in metallic substrates are commonly ferritic stainless steel alloy with chrome, aluminium and rare earth  
88 metals. Typical CPSI values for these metallic monoliths lie in the range 400-600 CPSI with 0.002 in wall  
89 thickness[16]. Another advantage of metallic monoliths is their high thermal conductivity and low heat capacity,  
90 which allow faster heating during the engine start-up thereby minimising the light-off time[22]. It is also  
91 possible to construct the channels with corrugated foils to induce turbulent flow and increase the mass transfer  
92 and therefore catalyst efficiency[23]. One of the main disadvantages of metallic monoliths is their higher  
93 manufacturing cost. The thermal expansion coefficient is much greater for metallic substrates which means they  
94 require special bonding techniques to adhere washcoat onto the metal surface[24].

95 Another technology that has been developed to improve the efficiency of catalytic converters employs a  
96 periodical reversal of gas flow through the catalyst. This technology traps the heat energy from inside the  
97 monolith to increase the catalyst operating temperature. This has been used in the purification of industrial off-  
98 gases containing VOCs[25]; oxidation of methane and CO emitted from dual LNG dual-fuel diesel engines[26,  
99 27]; NO<sub>x</sub> reduction from diesel engines; and emission control during cold start of automotive engines[28]. The  
100 main drawback is that the performance of the system strongly depends on the temperature of the exhaust and  
101 catalytic reactor. It has been reported that the technology fails to operate efficiently if the reactor temperature  
102 or concentrations of HC and CO are too low[27].

103 Introducing turbulent flow is a promising approach to increase catalytic converter efficiency and/or facilitate a  
104 more uniform temperature profile across the catalytic converter[29, 30]. In a conventional extruded monolith,  
105 the flow in the frontal section is a jet flow; however it is fully laminar inside the narrow channels,. It is well  
106 known that in laminar flow the catalytic reaction is diffusion limited; therefore, different methods have been  
107 proposed to increase turbulence in the inlet flow (not inside the channels). One method is to add a device before  
108 the monolith to induce turbulence to the gas, prior to entering the channels. Agrawal et al.[31], showed that the  
109 turbulence device with a swirl blade configuration is effective in improving the conversion efficiency of the  
110 catalytic converter, with lower backpressure relative to other configurations.

111 Another approach is to create the turbulent flow inside the channels. Figure 2 shows two structures which was  
 112 proposed by Brük et al. [32], longitudinal structure (LS) and perforated structure (PS). In the LS structure, the  
 113 monolith is divided into disks that lie perpendicular to the direction of gas flow to generate turbulence on the  
 114 frontal section of the monolith. Despite having an efficient catalytic converter, the method was not efficient for  
 115 mass production, due to the high production cost and complicated canning process. In the PS structure, the  
 116 authors employed corrugated and flat metallic foils containing 8 mm diameters holes to facilitate radial flow  
 117 inside the channels, which increased conversion and lowered backpressure. However, the differences in thermal  
 118 expansions between metallic substrates and washcoat have minimised the usage of metal based catalytic  
 119 converters in original equipment manufacturer (OEM) diesel engines, which makes ceramics the most  
 120 promising material for such applications.

121 Figure 2 Longitudinal Structure (left) and Perforated Structure (right) for enhanced mass flow in catalytic converter.[32, 33]  
 122 3D printing has attracted more attention in recent years as a versatile and low-cost technology for rapid  
 123 casting/prototyping of a variety of materials, including ceramics.[34, 35] Thanks to its almost unlimited axial  
 124 flexibility, this technique enables rapid production of customised shapes, the design of which can vary through  
 125 each of all three spatial dimensions. In the case of catalytic converter substrates, the versatility offered by 3D  
 126 printing greatly increases the range and complexity of channel structures that are not available using  
 127 conventional extrusion methods. A number of 3D printing techniques are suitable for ceramics, the choice of  
 128 which is determined by whether the ceramic material is the form of slurry, powder, bulk solid or paste. Examples  
 129 of available technologies for 3D printing of ceramics are liquid deposition modelling (LDM); laminated object  
 130 manufacturing (LOM); for bulk solid/paste materials, stereolithography (SLA); digital light processing (DLP);  
 131 two-photon polymerisation (TPP); ink-jet printing (IJP); direct ink writing (DIW) and three-dimensional  
 132 printing (3DP) for slurry based materials; selective laser sintering (SLS); and selective laser melting (SLM) for  
 133 ceramic powder[36]. Here we report the design and printing of substrate structures with greater complexity than  
 134 those available in conventional honeycomb arrangements with straight channels and evaluate their performance  
 135 in the catalytic oxidation of methane.

## 2. Experimental method

### 2.1 Substrate 3D printing

Small samples (Ø2.0 cm x H2.0 cm) were printed using cordierite precursors on a WASP 4070 ceramic 3D printer with nozzle diameter 0.7 mm. The technique for deposition of material is LDM (similar to robocasting), which consists of depositing layers of ceramic material (cordierite paste) until the model is formed. Cordierite was synthesised according to a solid-state reaction of cordierite precursors based on a composition available in literature[37, 38]. A paste was prepared by dry mixing of cordierite precursors in powder form according to Table 1, followed by adding water and ethylene glycol (20% of solid weight) with ratio 6:1. The mixture was kneaded until a uniform paste was formed. The paste was then used to print the substrates.

Table 1 Composition of cordierite precursor for solid mixing.

Compound	Talc	Kaolin	Al <sub>2</sub> O <sub>3</sub>	B <sub>2</sub> O <sub>3</sub>	Cordierite
Weight (%)	35.4	46.7	12.9	1.7	3.3

Printed samples were dried at room temperature for 24 hours, heated at 1 °C.min<sup>-1</sup> ramp rate and sintered at 1200 °C to form the cordierite phase. Subsequently, the substrates were washcoated according to the method described in section 2.2. The weight of washcoat on the substrates was adjusted to be around 0.1 g.

### 2.2 Catalyst preparation

The catalyst washcoat was chosen to be applicable to auto emission control. The catalyst contained Pd:Pt with 1:1 ratio doped on Al<sub>2</sub>O<sub>3</sub>/HY zeolite and promoted by cerium, zirconium and titanium oxide. The zeolite used in this formulation was prepared using a geothermal silica source which we previously found to be active in methane oxidation[39]. This activity is attributed to the presence of sodium ions in the structure of the zeolite[40].

The washcoat catalyst was prepared according to the following procedure:

- Support suspension: 1000 mg of support powder was prepared by mixing HY Zeolite,  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> (Sigma-Aldrich, activated, neutral), TiO<sub>2</sub> (Millennium PC500), CeO<sub>2</sub> (Sigma-Aldrich, nanopowder <25nm particle

size), and ZrO<sub>2</sub> (Sigma-Aldrich, 5µm, 99%) with mass ratio 12:3:3:1:1, respectively. 100ml of water was added to the solid powder and stirred, and the pH was adjusted to 11 by adding NH<sub>4</sub>OH solution.

- Precious metal solution: 290 mg Pd(NO<sub>3</sub>)<sub>2</sub>.H<sub>2</sub>O (Alfa Aesar, 99.8%) and 283 mg K<sub>2</sub>PtCl<sub>4</sub> (Precious Metals Online, 99 %), were dissolved in distilled water in two separate 50 ml volumetric flasks, followed by ultrasonic treatment for 15 min. Precious metal solution was added dropwise to the support suspension, stirred for 2 hours followed by ultrasonic treatment for 15 min. The resulting suspension was used as washcoat for the substrate. The solid powder was extracted from the catalyst suspension by filtration and converted to pellet form by compression, crushing and finally sieving.
- Both catalyst pellets and washcoated 3D printed substrates were dried at 50 °C for 24 hours and calcined at 550 °C for 8 hours.

## 2.3 Catalyst characterisation

X-ray diffraction (XRD) analysis of powder catalyst was performed at ambient conditions using a Panalytical X'Pert Powder diffractometer with Cu K $\alpha$  radiation ( $\lambda = 1.5406 \text{ \AA}$ ). The diffraction pattern was recorded in the range 5 to 120° with a step size 0.013 and step time 200 s, using an X-ray tube operated at 45 kV and 40 mA with fixed 4° programmable anti-scatter slit. Scanning electron microscopy (SEM) images were recorded using a ZEISS Supra 40VP microscope. Prior to imaging, the samples were sputter-coated with a thin layer of gold. Nitrogen adsorption/desorption measurement was carried out on a Micromeritics ASAP 2020 Surface Analyser at 77 K. Samples were degassed under vacuum ( $p < 10^{-5}$  mbar) for 3 hour at 300 °C prior to analysis. BET surface areas were calculated in the relative pressure range 0.05-0.30.

## 2.4 Catalyst testing

To investigate the effect of structure on substrate performance, washcoated samples were tested under similar conditions in methane oxidation. The feed contains 5 vol.% CH<sub>4</sub>, 10 vol.% O<sub>2</sub>, 85 vol.% He with GHSV of 400, 800 and 1200 h<sup>-1</sup>. The weight of catalyst either in pellet form or on the substrate is 0.1 g. When in pellet form, the catalyst was mixed with glass beads, which acted as a diluent to prevent formation of hotspot zones on the catalyst by reducing its activity without affecting the fluid flow through the catalyst bed[41].

## 2.5 CFD analysis

The effect of structure on fluid dynamics, turbulence and backpressure was analysed using ANSYS Fluent v19.1. The fluid domain was meshed using a tetrahedron method with refined mesh near the walls (Figure 3). Realizable k-epsilon turbulence with default constants were used as a model. Air at room temperature and pressure was used as the fluid and cordierite as the solid material. Boundary conditions are as follow: inlet velocity  $0.0066 \text{ m.s}^{-1}$  (corresponding to GHSV=1200  $\text{h}^{-1}$ ),  $k$  (turbulent kinetic energy) =  $0.0015 \text{ m}^2.\text{s}^{-2}$ ,  $\varepsilon$  (turbulence dissipation rate)= $0.00679 \text{ m}^2.\text{s}^{-3}$ , outlet gauge pressure = 0 Pa, temperature = 20 °C. Equations to calculate  $k$  and  $\varepsilon$  are as follows[42]:

$$k = \frac{3}{2}(u_{avg}I)^2 \quad I = 0.16Re^{-\frac{1}{8}} \quad \varepsilon = \frac{C_u^{\frac{3}{4}}k^{\frac{3}{2}}}{l} \quad l = 0.07L$$

where  $C_u$  is an empirical constant specified in the turbulence model, which is approximately 0.09, and  $L$  is the diameter of the pipe. Number of nodes and elements are listed in Table 2.

Table 2 Number of nodes and elements for different structures

Structure	Number of Nodes	Number of Elements
30 °	1136074	5100584
45 °	1004929	4694231
60 °	1038631	4300399
90 °	1572989	2192526
CPSI 400	248694	1468540

Figure 3. Fluid domain mesh for CFD analysis.

### 3. Results and discussion

#### 3.1 Ceramic 3D printing

SketchUp was used as the 3D modelling software to design the different structures. The structure is made of layers, which are printed at an offset angle to the preceding layer, and so on, vertically upwards (Figure 4). A conventional honeycomb substrate with straight channels was also designed for comparison purposes. The CAD (computer-aided design) were later used in slicing software to generate the g-code for 3D printing.

Figure 4. General structure and cross sectional view of 3D printed ceramic substrates.

Figure 5 3D printed substrates (Ø2.0 cm x H2.0 cm) with different layer rotation offset (after sintering).

219 Figure 5 shows optical images of 3D printed substrates with different rotation angles after sintering (but before  
220 washcoating). The SEM images of samples after washcoating are shown in Figure 6. Figure 6.a. shows SEM  
221 image of substrate with 45 ° offset angle. These samples show less open area, after washcoat, compared to 90 °  
222 (Figure 6.b.) or the commercial sample (Figure 6.c.). Figure 6.d. shows the washcoat in more detail. It should  
223 be noted that the 3D printed monolith was prepared with relatively thick walls; this is due to limitations in  
224 extrusion of material through the nozzle using the LDM method. From SEM images on Figure 6, this value is  
225 around 0.59 mm, equivalent to CPSI 100. The wall thickness for the commercial substrate with CPSI 400 is  
226 0.18 mm which is 70% less than the 3D printed sample.

227 Honeycomb monolith structures have been manufactured and tested by 3D printing of ceramic material  
228 especially cordierite using robocasting or LDM methods[43-45]. Other 3D printing methods such as DLP has  
229 shown promising results to manufacture structures with thinner walls and more details. However, material  
230 properties (e.g. ceramic particle size and resin formulation) or printing parameters (e.g. layer thickness and  
231 exposure time) need to be optimised for a successful print with desirable mechanical properties[46].

Figure 6 SEM imaging of 3D printed substrates; a) 45 °, b) 90 °, c) commercial, d) catalyst washcoat on substrate.

### 3.2 Catalyst characterisation

The properties of the fresh and used catalyst support powder, measured by nitrogen adsorption-desorption at 77 K, are listed in Table 3.  $S_{BET}$  is the surface area calculated by BET method,  $V_t$  is the total pore volume calculated at  $P/P^*=0.98$ ,  $V_{mes}$  is the volume of mesopores calculated using BJH method during desorption,  $V_{mic}$  is the volume of micro-pores calculated using t-plot method during desorption and  $d_{BJH}$  is the average diameter of mesopores calculated using BJH method during desorption. Figure 7 illustrates the adsorption-desorption isotherm of the catalyst washcoat before and after reaction. The graph is consistent with typical type IV adsorption isotherm with H3 hysteresis. Such isotherms are normally for aggregates of plate-like particles that form slit-like pores[47]. Overall, there were slight decreases in porosity characteristics, particularly so for  $V_{mic}$  which may have been caused by carbon deposition and/or metal nanoparticles sintering within the micropores.

Table 3 Physical properties of catalyst support powder measured by N<sub>2</sub> adsorption-desorption at 77 K.

	$S_{BET}(\text{m}^2.\text{g}^{-1})$	$V_t(\text{m}^3.\text{g}^{-1})$	$V_{mes}(\text{m}^3.\text{g}^{-1})$	$V_{mic}(\text{m}^3.\text{g}^{-1})$	$d_{BJH}(\text{nm})$
Fresh	363	0.44	0.28	0.16	14.3
Used	311	0.36	0.27	0.09	13.7

Figure 7 N<sub>2</sub> adsorption/desorption isotherms of fresh and used (TOS = 90 h) catalyst support powder.

Figure 8 shows the the XRD pattern of catalyst washcoat before and after impregnation. The XRD confirms the characteristic crystallinity of Faujasite type zeolite, Al<sub>2</sub>O<sub>3</sub>, CeO<sub>2</sub> and ZrO<sub>2</sub>; the TiO<sub>2</sub> peaks are not visible due to their relatively weak intensities, low concentration of TiO<sub>2</sub> in the overall sample and overlap with other reflections. There was a noticeable decrease in the peak intensities for zeolites. This is due to the partial structural decay of zeolites resulting from the metal impregnation and additional associated calcination step. Moreover, Pd or Pt peaks are not detected due to their low content and implied high dispersion. There was

practically no change observed in the  $d$ -spacing values of the zeolite, which proves that the zeolitic crystalline structure was unchanged after impregnation. Figure 9 shows TEM images of fresh catalyst washcoat and after 90 hours consecutive stability testing. The stability tests were conducted using a reactant stream comparable to an engine exhaust stream, including the presence of steam i.e. 450 °C, 5% CH<sub>4</sub>, 20% O<sub>2</sub>, 3% CO, 7% CO<sub>2</sub>, 6% H<sub>2</sub>O, GHSV 1200 h<sup>-1</sup>). Although slight sintering is observed for only very fine particles, the metal particles size has not been changed significantly. This confirms the catalyst stability against sintering for an extended time.

Figure 8 XRD pattern of catalyst support powder, before and after precious metals impregnation.

Figure 9. TEM images of catalyst washcoat, a) fresh catalyst (left); after 90 hours stability test (right).

### 3.3 Methane oxidation

Methane was practically unreactive from 200-250 °C, while the conversions increased continuously thereafter from 250 °C. Figure 10a-c show that the pellets are catalytically active and that no significant change in activity was observed at different GHSVs.

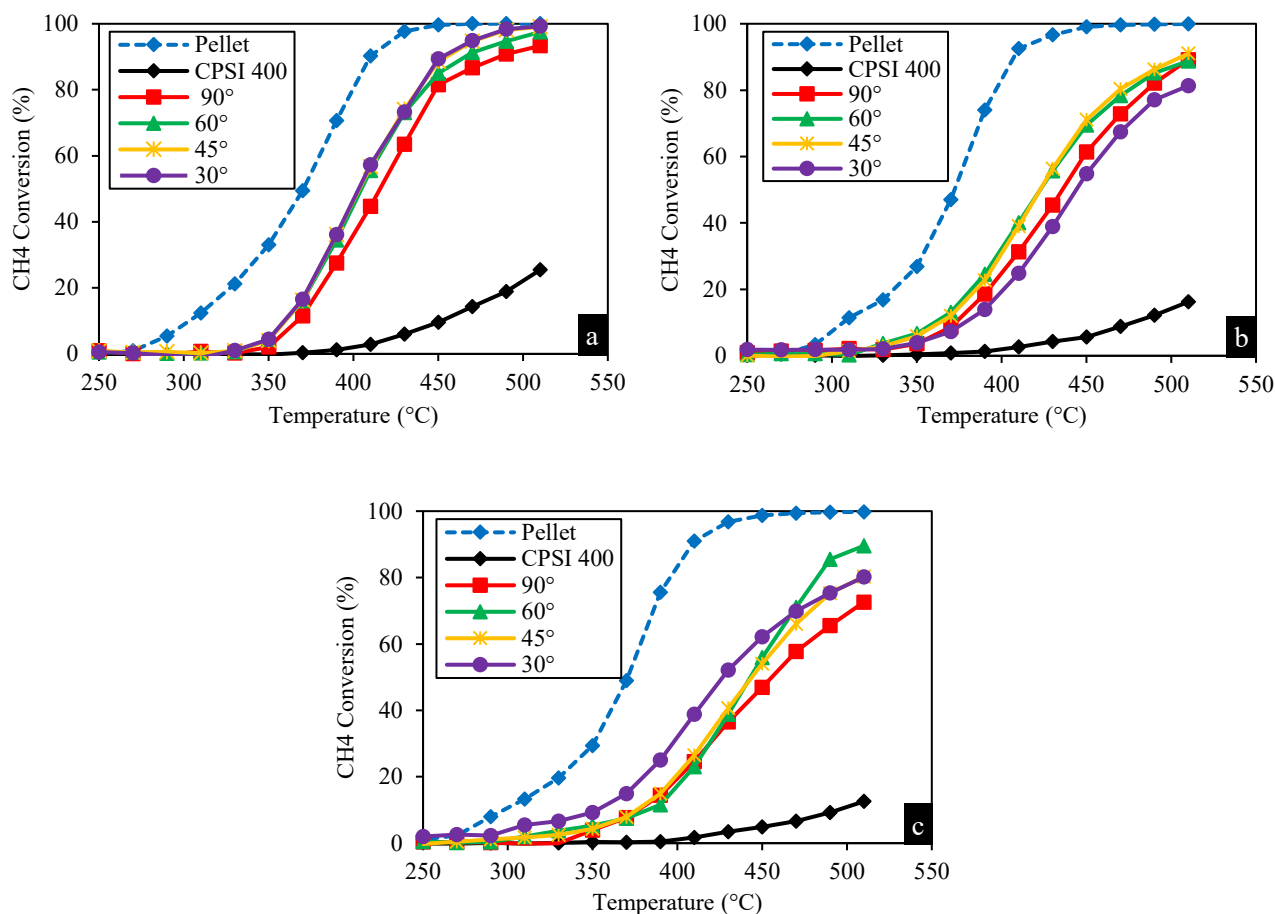

Figure 10 Effect of structure on methane conversion; a) GHSV 400 h<sup>-1</sup>, b) GHSV 800 h<sup>-1</sup>, c) GHSV 1200 h<sup>-1</sup> (CH<sub>4</sub>: 5%, O<sub>2</sub>: 10%, He: 85%).

All 3D printed substrates showed superior catalytic activity than the conventional CPSI 400 structure. For instance, at 510 °C and GHSV of 1200 h<sup>-1</sup>, methane conversion is 12.6% on the commercial structure, while this value is 72.6% for the 90 ° structure, 80.1% for both 30 ° and 45 °, and 89.6% for the 60 °. Another interesting observation is the effect of GHSV on performance of 3D printed substrates. At low GHSV (e.g. 400 h<sup>-1</sup>), all 3D printed substrates have a very similar conversion at temperature range of 350-510 °C, however, increasing the flow rate influenced their catalytic performance. For example, at GHSV of 1200 h<sup>-1</sup> the 30 ° structure shows better conversion at the temperature range of 300-450 °C, while the 60 ° structure shows the highest conversion at temperatures above 450 °C. At high velocities, the 90 ° structure, which is the most similar in structure to the conventional substrate, shows the lowest activity compared to the other 3D printed structures. In general, these results clearly show that increasing complexity of the channel structure in the 3D printed substrates increases catalytic activity by altering the flow regime and enhancing the mass transfer/turbulence.

Incidentally, the catalyst activity was lower when washcoated on the substrates, relative to pellets, due to the void volume and heat transfer into the substrate, which lowered the overall catalyst temperature. The increased catalytic activity is also rationalised by the higher surface areas in the 3D printed substrates (Table 4), which result from the unique arrangement of 3-dimensionally oriented layers, thereby exposing a higher proportion of substrate to the external surface. To keep the experimental conditions same, the amount of catalyst loading on the substrate kept similar (e.g. around 0.1 mg). The preparation of a substrate with lower wall thickness and higher CPSI using more advanced 3D printing technology, e.g. SLA or DLP, will improve the catalytic performance; such trials are currently under investigation by the authors.

Table 4. Relation between structure and physical properties of the substrates (wall thickness of 3D printed substrate = 0.59 mm, wall thickness of commercial substrate = 0.18 mm).

Structure	Surface Area (m <sup>2</sup> .L <sup>-1</sup> )	Weight of washcoat (mg)	Weight of substrate (mg)
30 °	3.628	0.104	8.538
45 °	3.633	0.103	8.407
60 °	3.630	0.104	8.286
90 °	3.629	0.095	7.755
CPSI 400	2.876	0.097	2.285

Figure 11 compares the velocity magnitude vectors for both conventional and 3D printed structures. Generally, the 3D printed structure benefits from a higher velocity magnitude and therefore higher turbulence inside the channels. The dark blue colour represents low velocity vectors, which mostly occurs near the walls, while orange and red colours represent high velocity vectors which occurs in the centre of the channels. These regions (orange and red colours) do not exist for commercial substrates and are in the order 30 ° > 45 ° > 60 ° > 90 ° for the 3D printed substrates. Therefore, we tentatively assign the higher conversion of methane over the 30 ° substrate in the temperature range of 300-450 °C to its higher turbulence at this GHSV. It should be noted that the 60 and 90 ° exhibit a lower degree of irregularity compared to 30 ° and 45 °.

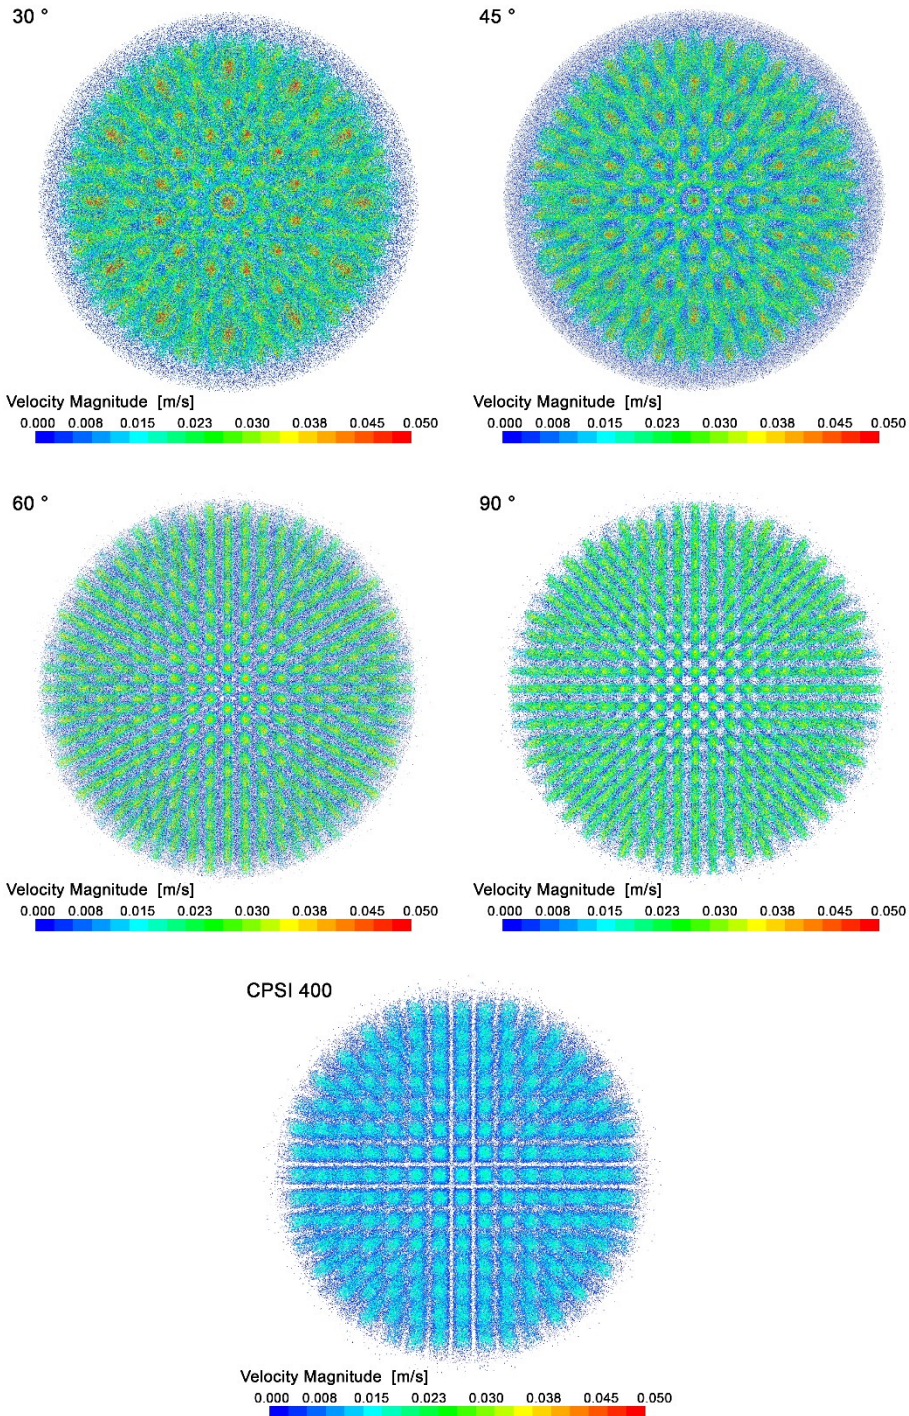

Figure 11. Frontal view of velocity magnitude vectors in the fluid domain for different substrate structures (Fluid: air at 25 °C; GHSV: 1200 h<sup>-1</sup>).

Turbulent kinetic energy is used to represent the intensity of turbulence in a given region. Figure 12 illustrates the turbulent kinetic energy vector inside the channels across the flow direction. While this value is relatively small (blue colour) and mainly in one direction for the conventional structure, higher turbulent kinetic energy and in different directions is observed for the 3D printed structures. Orange and red vectors are close to the walls, especially where the walls intersect. This is due to the rotation of the wall across the z-axis which leads to the formation of a complex structure. It also can be concluded that the magnitude of turbulent kinetic energy

319 is less for more regular structures (e.g. 60 ° or 90 °). The distribution of turbulent kinetic energy is also more  
 320 uniform for such structures.

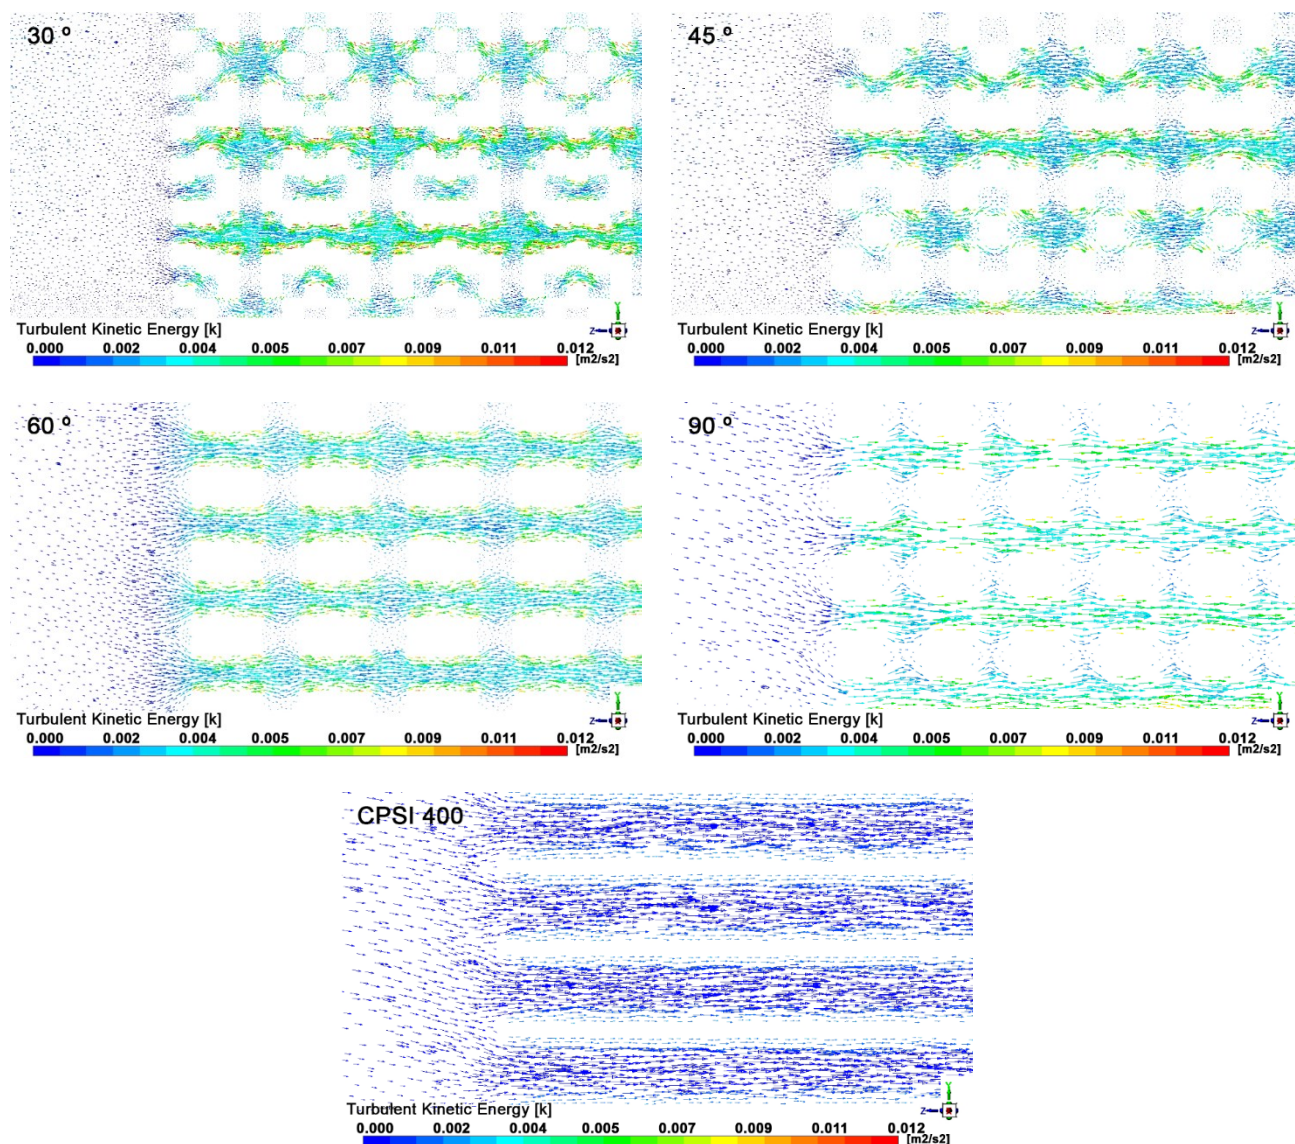

Figure 12. Profile of the turbulent kinetic energy vector inside the channels (GHSV=1200 h<sup>-1</sup>).

Static pressure profile across the z-axis of substrates is shown in Figure 13. The maximum change in static pressure is observed for the more complex structures, particularly the 30 ° and 45 °, which provide the most turbulence. Pressure drops over 60 ° and 90 ° structures are milder compared to the 30 ° and 45 ° structures but still more than that for the straight-channelled conventional structures.

Figure 13 Static pressure profile across the substrate with different structures (GHSV=1200 h<sup>-1</sup>).

### 3.4 Backpressure measurement

An experimental method was used to measure the backpressure over different structures at different air inlet velocities. Figure 14 compares the backpressure over different substrate structures for the inlet velocity up to 1.0 m.s<sup>-1</sup>. As expected, the 3D printed structures show higher backpressure compared to the conventional substrates with straight channels. This is due to induced turbulence in these structures, which causes irregular fluctuations and mixing, in contrast to the laminar flow regime with higher velocity inside the straight channels. The backpressure is much less for the structures with more regularity (e.g. 60 ° and 90 °). This is in line with the CFD analysis results where the 30 ° and 45 ° structures exhibited more turbulence.

The highest contribution to backpressure in a real diesel engines is from the diesel particulate filter (DPF) in the after treatment system. The maximum recommended exhaust backpressure by VERT (Verification of Emission Reduction Technologies) for DPF varies. The values are 40 kPa for engines with less than 50 kW power, 20

347 kPa for 50-500 kW engines and 10 kPa for engines with power more than 500 kW[48]. The results in Figure 14  
 348 suggest that backpressure for the 60 ° and 90 ° are close to that for the commercial substrate, which makes these  
 349 structures suitable for commercial applications.

Figure 14 Effect of inlet gas velocity on backpressure over different structures.

#### 4. Conclusions

354 Catalytic converter substrates prepared by 3D printing of cordierite showed improved catalytic activity in  
 355 methane oxidation relative to a conventional commercial honeycomb structure. It was shown that the substrates  
 356 with irregular structures had higher conversion due to the higher turbulent kinetic energy in these structures.  
 357 The findings provide proof of concept evidence that 3D printing is a suitable means of designing a catalytic  
 358 converter prototype with higher reaction activity than currently available. The findings have implications for  
 359 the design and potential mass production of new catalytic materials.
