Comparison of methods of calculating dynamic strength index

32 Abstract

Purpose: To determine the reliability and variability of dynamic strength index (DSI) calculated from squat jump (SJ) (DSI-SJ) versus countermovement jump (CMJ) (DSI-CMJ) peak force (PF) and to compare DSI values between methods. Methods: Male youth soccer and rugby league players (n = 27; age = 17.2 ± 0.7 years; height = 173.9 ± 5.7 cm; body mass = 71.1 ± 7.2 kg) performed 3 trials of the SJ, CMJ and isometric mid-thigh pull (IMTP), on two separate days. DSI was calculated by dividing the PF during each jump by the IMTP PF. **Results:** DSI-SJ exhibited moderate (intraclass correlation coefficient (ICC) = 0.419) within-session reliability and high variability (percentage coefficient of variation (%CV) = 15.91) during session one; however, this improved noticeably during session two (ICC = 0.948; %CV = 4.03). Contrastingly, DSI-CMJ showed nearly perfect within-session reliability (ICC = (0.920-0.952) and low variability (%CV = 3.80-4.57) for both sessions. Moreover, DSI-SJ values demonstrated a small yet significant increase between sessions (P = 0.01, d = 0.37), whereas only a trivial and non-significant increase was observed for DSI-CMJ between sessions (P = 0.796 d = 0.07). Between-session reliability was very high for the DSI-SJ (ICC = 0.741) and nearly perfect for the DSI-CMJ (ICC = 0.924). There was no significant or meaningful difference (P = 0.261; d = 0.12) between DSI-SJ (0.82 ± 0.18) and DSI-CMJ (0.84 \pm 0.15). **Conclusions:** Practitioners should use DSI-CMJ as it is a more reliable measure than DSI-SJ, although it produces similar ratios.

73 Introduction

54 Strength has been shown to underpin performance in numerous athletic tasks,¹ including 55 sprint,²⁻⁴ jump^{5, 6} and change of direction performance.⁶⁻⁸ However, strength is commonly 56 assessed using a variety of methods, including one repetition maximum (1RM) testing, during 57 different compound exercises,^{2-4, 6} and peak force (PF) assessed during the isometric mid-thigh 58 pull (IMTP)^{5, 9, 10} and the isometric squat.¹¹

79 While 1RM assessments are easy to conduct, can be incorporated within scheduled training sessions, demonstrate high reliability^{12, 13} and are regularly used to prescribe training intensity, 80 such testing can be fatiguing and only provide a maximal load lifted. In contrast, minimal 81 82 fatigue is likely to result from performance of the IMTP, and additional information regarding rate of force development (RFD)^{14,15}, impulse, and force produced across specific epochs (e.g. 83 0-100, 0-150, 0-200 ms) can be determined ¹⁵⁻¹⁷. Such information may provide the practitioner 84 with greater information regarding the athlete's ability to express not only maximal force, but 85 86 their ability to rapidly produce force. It is worth noting however, that the reliability of the RFD calculation during the IMTP has been questioned, with peak RFD over short epochs (2-50 ms) 87 being suggested to be the most reliable of the available measures.¹⁴ 88

To provide greater insight into an athlete's training status, the ratio of ballistic PF, produced 89 during a squat jump (SJ) or a countermovement jump (CMJ), and PF during the IMTP has been 90 discussed within the literature.^{9, 10, 18-21} This ratio is commonly referred to as the dynamic 91 strength index (DSI) or the dynamic strength deficit and has been reported to be highly reliable 92 93 (intraclass correlation coefficient (ICC) 0.952-0.987) with low variability (2.01-4.60% 94 coefficient of variation percentage (CV%)).^{19, 22} Recommendations for interpreting the ratio suggest focusing on ballistic force production when the ratio is low (< 0.60) and maximal 95 strength development when the ratio is high (> 0.80).¹⁹ However, it is important to note that in 96 athletes with low relative strength, developing relative strength may be more advantageous 97 than focussing on achieving a specific ratio.^{23, 24} 98

99 As the calculation of DSI using both PF attained during the SJ and CMJ has been reported within the literature, it is important to determine whether the differences in these methods 100 101 affects not only the reliability and variability of the measures, but also the resultant DSI ratios. Due to the CMJ incorporating the stretch-shortening cycle (SSC), it is likely that the PF will 102 be higher when compared to the PF attained during the SJ.^{25, 26} Additionally, it is not clear 103 from the studies that have used the CMJ, if the PF was obtained during the braking or 104 propulsive phase which may affect the resultant PF,^{9, 10, 20, 21} as the phase in which PF occurs 105 differs between individuals. The aim of this study, therefore, was to determine the reliability 106 and variability of DSI ratios when calculated based on PF attained during the SJ (DSI-SJ) and 107 CMJ (DSI-CMJ) and to compare the resultant DSI values between methods. It was 108 109 hypothesised that both methods would be reliable, both within- and between sessions, with greater values derived from DSI-CMJ due to the higher PF compared to the DSI-SJ calculation, 110 due to the use of the SSC during the CMJ. 111

112

114 Methods

115 Subjects

116 Male professional youth soccer and rugby league players (n = 27; age = 17.2 ± 0.7 years; height 117 = 173.9 ± 5.7 cm; body mass = 71.1 ± 7.2 kg) participated in this study. All participants 118 provided written informed consent, with consent from the parent or guardian of all subject 119 under the age of 18 years. The study procedures were approved by the University Institutional 120 Review Board, and procedures conformed to the Declaration of Helsinki.

121

122 **Procedures**

To determine between session reliability, participants were assessed on two separate occasions, at the same time of day, 7 days apart. Testing was conducted within the first 4 weeks of the season, during which time all participants were in full training comprising all the elements of performance including four sport-specific skill based training sessions, plus two lower body resistance training sessions each week. At the time of testing, participants had completed a 4week strength mesocycle and were in the middle of a 4-week power mesocycle.

All athletes rested the day before testing and were asked to attend testing in a fed and hydrated state, similar to their normal practices before training. On arrival, all participants had their height (Stadiometer; Seca, Birmingham, United Kingdom) and body mass assessed (Seca Digital Scales, Model 707), measured to the nearest 0.1 kg and 0.1 cm, respectively. After performing a standardized dynamic warm up, which they were familiar with from all previous off-field training sessions, they performed three maximal effort SJ and CMJ trials, followed by three IMTPs, with five minutes of rest between each test.

Data from the second day of testing was used to compare between DSI-SJ and DSI-CMJ andto determine any relationships between the two methods.

138

139 Jump Testing

140 Both the SJ and CMJ trials were performed with the subjects standing on a force platform (type: 141 9286AA, dimensions 600 mm x 400 mm, Kistler Instruments Inc., Amherst, NY, USA) 142 sampling at 1000 Hz, interfaced with laptop computer running Bioware software (version 5.11, 143 Kistler Instruments Inc., Amherst, NY, USA). Subjects were instructed to stand still for the 144 initial one second of the data collection period (known as the silent period immediately prior to performing the jumps)^{27, 28} to allow for the subsequent determination of body weight. The 145 146 raw, unfiltered, vertical force-time data for each jump trial were exported as text files and analysed, in line with previous recommendations to minimise sources of error, ²⁹ using a 147 customised Microsoft Excel spreadsheet (version 2016, Microsoft Corp., Redmond, WA, 148 149 USA).

All jumps were performed whilst the subjects kept their hands on their hips, with any jumps
that were inadvertently performed with the inclusion of arm swing omitted and additional trials
performed after one minute of rest. For the SJ, subjects were instructed to squat down to a self-

153 selected depth (approximately 90°), pause for a count of three and then jump as fast and as high 154 as possible, without performing any preparatory countermovement. Resultant force-time data was visually inspected to determine if any countermovement had been performed, and if it had, 155 subjects repeated the trial after one minute of rest. Subsequent analysis of the SJ force-time 156 157 data revealed that no trial exceeded the threshold used to determine a countermovement (five times the standard deviation of body weight, as derived during the silent period), ^{27, 30} as 158 159 described below. For the CMJ subjects were instructed to aim to jump as high as possible, 160 performing a rapid dip, to a self-selected depth, which they believed would achieve their 161 greatest jump height. To aid the standardisation of instructions and procedures all, assessments 162 were performed by the same experienced researcher.

163 The start of the jumps were identified in line with current recommendations where the onset of 164 movement for each jump trial was considered to have occurred 30 milliseconds prior to the instant when vertical force had reduced (CMJ) or increased (SJ) by five times the standard 165 deviation of body weight, as derived during the silent period.^{27, 30} The interpretation of the CMJ 166 force-time curves attained in this study is in line with recent research.³⁰ Instantaneous centre 167 168 of mass (COM) velocity was calculated by dividing vertical force (excluding body weight) by 169 body mass and then integrating the product using the trapezoid rule. The concentric phase of the CMJ and SJ was then defined as occurring between the instant at which COM velocity 170 exceeded 0.01 m·s⁻¹ and take-off.³⁰ The instant of take-off was defined as the instant in time 171 when vertical force was less than five times the standard deviation of the flight force following 172 the onset of movement.²⁷ It was important to clearly identify the concentric peak force 173 (propulsive phase) during the CMJ rather than the eccentric peak force (braking phase) (Figure 174 175 1), to ensure that this is comparable with the SJ which has no eccentric phase. Concentric PF 176 was defined as the maximum value attained during the propulsion phase of the jumps. Jump height was derived from vertical velocity at take-off with take-off.^{28, 30} 177

180

181

182 183

184 Isometric Mid-Thigh Pull Testing

The IMTP was performed using a portable force platform (type: 9286AA, dimensions 600 mm 185 x 400 mm, Kistler Instruments Inc., Amherst, NY, USA) sampling at 1000 Hz, interfaced with 186 laptop computer running Bioware software (version 5.11, Kistler Instruments Inc., Amherst, 187 188 NY, USA). Raw force-time was subsequently exported and analysed in a custom-made 189 Microsoft Excel spreadsheet. Subjects adopted a posture which replicated the position at which they would start the second pull phase of the clean, with their knee and hip angles within 140-190 150°, in line with previous research.^{31, 32} An immovable, collarless cold rolled steel bar was 191 positioned around mid-thigh, just below the crease of the hip, using a portable IMTP rig 192 193 (Fitness Technology, Adelaide, Australia). Once the bar height was established, the athletes 194 stood on the force platform, and their hands were strapped to the bar using standard lifting 195 straps. The height of the bar and the resultant joint angles were replicated between trials and 196 between testing sessions.

197 Each athlete performed two warm-up pulls, one at 50% and one at 75% of the athlete's perceived maximum effort, separated by one minute of rest. Once body position was stable 198 (verified by visual inspection of the force trace), the subject was given a countdown of "3, 2, 199 1, Pull." Minimal pretension was allowed to ensure that there was no slack in the subject's 200 201 body or IMTP rig before initiation of the pull. Athletes performed three maximal IMTP, with 202 the instruction to pull against the bar with maximal effort pulling as fast and hard as possible, 203 and push the feet down into the force platform. Each maximal IMTP trial was performed for 204 five seconds, and all athletes were given strong verbal encouragement during each trial. Two minutes of rest was given between the maximal effort pulls. Trials were repeated if the PF 205 values varied by >250 N in line with previous research.^{16, 17, 31, 32} The maximum force recorded 206 from the force-time curve during the five-second IMTP trial was reported as the PF. Each of 207 208 the 3 trials was used to determine within session reliability, with the mean of the best two trials, 209 based on PF, used to compare between sessions, in line with previous research.^{31, 32}

The DSI was calculated by dividing jump PF by IMTP PF, with DSI-SJ using PF from the SJand DSI-CMJ using PF from the CMJ.

212

213 Statistical Analyses

214 Within- and between-session reliability of dependent variables was examined using the ICC, 215 and typical error of measurement (TE) expressed as a CV%. A CV of $\leq 10\%$ was considered to be reflective of acceptable variability.³³ Specifically, a two-way random effects model ICC 216 217 was used to determine within- and between-session reliability (internal consistency), with 218 paired samples t-tests and Cohen's d effect sizes used to determine if any differences occurred 219 between days, between the two methods of calculating DSI (DSI-SJ and DSI-CMJ) and 220 between PF achieved during the SJ and CMJ. Finally, Pearson's correlation was performed to 221 determine the relationship between both methods of assessing DSI, based on the resultant 222 values from the second day of testing, due to the higher reliability and lower variability 223 observed.

- To assess the magnitude of the ICC, the values were interpreted as low (<0.30), moderate (0.30-0.49), high (0.50-0.69), very high (0.70-0.89), nearly perfect (0.90-0.99), and perfect (1.0), respectively.³⁴ The magnitude of differences, as determined using Cohen's *d*, between sessions were classified as trivial (≤ 0.19), small (0.20 - 0.59), moderate (0.60 - 1.19), large (1.20 -
- 228 1.99), and very large (2.0 4.0).³⁵
- Normality of data was assessed by Shapiro–Wilk statistic and Q-Q plot analysis. Relationships between variables were determined using Pearson's product-moment correlation coefficients. Correlations were evaluated as follows: small (0.10 - 0.29), moderate (0.30 - 0.49), large (0.50 - 0.69), very large (0.70 - 0.89), nearly perfect (0.90 - 0.99), and perfect (1.0).³⁵ Statistical analyses were conducted using SPSS software (version 23.0; SPSS, Inc.) with an alpha level of $P \le 0.05$.

235

236 **Results**

DSI-SJ showed poor to moderate within-session reliability and high variability during session
 one; however, this improved during session two resulting in nearly perfect within-session

239 reliability and reduced variability (Table 1). In contrast, DSI-CMJ showed nearly perfect 240 within-session reliability and low variability for both testing sessions. Moreover, DSI-SJ demonstrated a small yet significant increase between sessions, whereas there was only a trivial 241 and non-significant increase in DSI-CMJ between sessions (Table 1). Between-session 242 243 reliability was very high for the DSI-SJ (ICC = 0.741) and nearly perfect for the DSI-CMJ (ICC = 0.924).244 245 246 [***Insert Table 1 here***] 247 248 249 250 There was no significant or meaningful difference (P = 0.261; d = 0.12) between DSI-SJ (0.82 251 \pm 0.18) and DSI-CMJ (0.84 \pm 0.15) (Figure 2), with a trivial and non-significant difference (P = 0.272; d = 0.19) in PF between the SJ (1789 \pm 350 N) and the CMJ (1854 \pm 345 N). The 252 253 results of Pearson's correlation analysis showed a very large positive relationship (r = 0.797; $R^2 = 0.635$) between DSI-SJ and DSI-CMJ (Figure 3). 254 255 256 257 [***Insert figure 2 here***] 258 259 260 261 262 [***Insert figure 3 here***] 263 264 265 266

267 **Discussion**

268 This study examined the reliability and variability of DSI-SJ and DSI-CMJ and compared the 269 resultant DSI values between methods. The DSI-SJ demonstrated improved reliability and 270 reduced variability between sessions, with a small and significant increase in values between 271 sessions. In contrast, there was no notable change in reliability and variability, or any meaningful or significant change in DSI-CMJ between sessions (Table 1), highlighting that 272 273 DSI-CMJ is a more stable method of assessing DSI compared to DSI-SJ. In contrast to our 274 hypotheses, there was no meaningful or significant difference between DSI-SJ and DSI-CMJ, with strong associations between DSI values determined using either method. 275

The greater variability and lower reliability observed for DSI-SJ is likely due to the difficulties associated with subjects consistently performing the SJ, without any countermovement, while attempting to jump as high as possible from a static squat position. It is therefore plausible that greater familiarisation with the SJ is required, which is likely to improve the reliability and reduce the variability of the performances, as observed during the second day of testing. In line with previous observations,^{25, 26} the inclusion of the countermovement during the CMJ resulted in a higher PF (3.6%) than that observed during the SJ, although this difference was trivial and non-significant. This non-significant difference in PF between the CMJ and SJ explain the
 trivial and non-significant differences in DSI-CMJ and DSI-SJ. In contrast, and as expected, a
 moderate and significantly greater jump height (12%) was achieved during the CMJ compared
 to the SJ, most likely due to the utilisation of the SSC resulting in increased force from the
 neurological potentiation and contribution from the elastic components.

The reliability and variability values in the current study are in line with those previously reported,^{19, 22} although the reliability of the DSI-SJ from session one shows notably lower reliability and much higher variability than presented in previous research.^{19, 22} This higher variability in the DSI-SJ, during session one, with an increased reliability and reduced variability during session two suggests a potential learning effect during the SJ. However, further research is needed to examine potential learning effects on SJ performance.

Given that CMJ testing is one of the most commonly used tools in athlete monitoring, it may be preferable to use DSI-CMJ ratios compared to DSI-SJ. In addition to DSI, the CMJ offers the opportunity to assess a variety of other performance characteristics that may not be possible with the SJ, namely the reactive strength index-modified.³⁶ Measuring both DSI and reactive strength index-modified will allow practitioners to assess both isometric and dynamic force production as well as the ability to utilise the SSC, respectively.³⁷ Such an approach may provide a more comprehensive assessment of an athlete's force production qualities.

The use of only three trials for each of the jumps, especially during the initial testing session, 301 302 is a potential limitation of this investigation, due to the low reliability and high variability 303 observed during the SJ. While such an approach is ecologically valid, and in line with applied 304 practice, it is suggested that future research consider applying a similar approach to that commonly used with the IMTP, ^{16, 17, 31, 32} where a specific force threshold (<250 N) is used to 305 determine if trials are acceptable. Additionally, future research should adopt a precise method 306 to determine and standardise the squat depth during the performance of the SJ, which may aid 307 308 in improving reliability and reducing variability of such performance.

309

310 **Practical Applications**

The results of the current study provide options to practitioners who would like to use DSI as an athlete monitoring tool. Both DSI-CMJ and DSI-SJ are reliable measures that give practitioners information regarding the ability of an athlete to produce maximal force during isometric and dynamic tasks. However, DSI-CMJ may provide a more consistent measurement as compared to DSI-SJ due to potential learning effects. Moreover, utilising a CMJ as opposed to a SJ may allow for the assessment of other force production characteristics.

Based on previous recommendations,¹⁹ it would appear that the athletes in the current study, on average, should focus on developing greater levels of muscular strength. However, it is important to note that training recommendations should be made on an individual basis. In addition, practitioners should be aware that while DSI ratios may help guide training decisions, a paucity of research has been completed on the long-term monitoring of DSI during lower and upper body tasks. Thus, further research is needed that focuses on how specific types of training affect DSI ratios and how DSI ratios relate to other sport performance characteristics.

325	Conclu	isions	
326 327 328 329	Based PF dur to PF compar	on the results of the current study it is suggested that DSI ratios are calculated based on ing the propulsion phase of the CMJ, as this is more reliable and less variable compared during the SJ. In addition, it is also easier to standardise performance of the CMJ red to ensuring that athletes do not initiate the SJ with any form of countermovement.	
330
