ABSTRACT: Reducing the precious metal content of water oxidation catalysts for proton-exchange-membrane water electrolyzers remains a critical barrier to their large-scale deployment. Herein, we present an engineered architecture for supported iridium catalysts, which enables decreased precious metal content and improved activity and conductivity. The improvement in performance at lower precious metal loading is realized by the deposition of a conformal layer of platinum nanoparticles on titanium dioxide (TiO_2) using a facile photoreduction method to prepare conductive layer coated supports (CCSs). Platinum nanoparticles are homogeneously dispersed on TiO_2 , and the conductivity of the subsequent catalysts with 39 wt % precious group metal loadings is significantly higher than the commercial 75 wt % loaded IrO_2 - TiO_2 catalysts. The conformal conductive layer also maintains an enhanced conductivity and electrochemical activity upon thermal annealing when compared to catalysts without the conductive layer and nonconformal heterogeneous conductive layer. The iridium mass activity from half-cell studies shows a 141% improvement for CCS supported catalysts at 42% lower loadings compared to the commercial catalysts. The conductive layer also improves the single cell electrolyzer performance at a similar catalyst loading in comparison to a commercial state-of-the-art catalyst. We correlate the physical properties of the engineered catalysts with their electrochemical performance in electrolyzers to understand structure–activity relationships, and we anticipate further performance improvements upon synthesis and materials optimizations.

INTRODUCTION

Electrochemical hydrogen generation has the potential to decarbonize the energy sector, enabling high renewable energy penetration through long-term energy storage and conversion.^{1,2} Additionally, deep decarbonization of industrial processes such as food production (ammonia synthesis), oil refining, and steel manufacturing can be realized if the “green” hydrogen from water splitting replaces hydrogen generated via routes that release carbon dioxide and other harmful byproducts.^{3,4} Annually, more than 95% of the 70 million tons of hydrogen is produced globally from hydrocarbons via steam methane reforming (SMR), water–gas shift, and coal gasification, among other processes.⁵ Electrolysis currently accounts for only 4% of hydrogen production. Proton-exchange-membrane (PEM)-based water splitting is one promising technology to displace SMR, however several cost-cutting measures are necessary to achieve the goal. One such measure is either to use curtailed renewable electricity or to reach power purchase agreements to reduce the feedstock cost (electricity). Eventual widespread deployment of PEM water electrolyzers (PEMWEs) is projected to render the electro-

chemical stack as the dominant cost, and the catalyst layers (CLs) as the most expensive components in the stack.⁶ Today, the CLs account for about 5% of the total cost of the stack, but this value is projected to increase as electrochemical hydrogen production is scaled up from kW to GW.⁷ Thus, by simultaneously lowering the feedstock costs and either replacing or lowering the platinum group metal (PGM) loadings in catalyst layers (CLs), it will be possible to lower the price of green H_2 to the SMR range.⁵ The techno-economic barrier emanating from high PGM loadings needs to be surmounted to enable large-scale (TW) electrochemically generated hydrogen to become economically competitive with hydrogen generation from SMR.⁷ The balance of plant and balance of cell costs are anticipated to decrease with high-

throughput manufacturing. Conversely, PGM costs are expected to remain high due to their limited abundance in the earth's crust, of which Ir is far rarer than Pt.⁸ To reduce the precious metal loading in PEM electrolyzers, various strategies including the use of non-PGM catalysts and engineering CLs with lower loadings of PGM catalysts supported on low-cost substrates have been explored.^{9–13} For example, King et al. recently reported the use of CoP as the cathode catalyst on PEMWE,¹⁴ and Alia et al. have shown the promising stability of various low Ir-loaded anode CLs.¹⁵ While a diverse library of non-PGM materials for cathodic hydrogen evolution reaction (HER) in PEMWE has been developed,¹⁶ analogous materials for anodic oxygen evolution reaction (OER) for PEMWE are yet to be identified.^{17,18} While the ultimate goal is to mitigate the usage of PGM catalysts, the need for short and midterm strategies to lower the PGM loading represents a critical development. To this end, one of the most promising strategies is to develop stable and conductive electrocatalyst supports akin to the carbon supports currently deployed in the CLs of PEM fuel cells.

Supports employed in PEMWE anodes must withstand the highly corrosive acidic (pH < 1) and oxidizing (>2 V) conditions.¹⁹ Furthermore, the support needs to be conductive. Under these conditions, most metals will readily oxidize and form insulating layers, while the few that can withstand the harsh conditions are just as expensive as Ir. While some metal oxides can withstand the corrosive conditions, most are poor conductors.^{20,21} Strategies to boost conductivity of metal oxides such as doping titanium oxide (TiO₂) and niobium oxide have shown improved conductivity over undoped oxides; however, their conductivity is lower than that of metals and the dopants are also known to leach out over time, thereby further reducing conductivity and stability.^{22,23}

As depicted in Figure 1a, for unsupported iridium, the bulk of the catalyst particle functions as the conductive support with

Figure 1. Schematics of: (a) bulk Ir catalyst, (b) traditional >50 wt % Ir shell coated on TiO₂ core, (c) proposed catalyst with Pt or Au intermediate layer between Ir and TiO₂, (d) nanostructuring strategy to reduce Ir loading without losing overall catalyst surface area, and (e) nanostructuring of both the catalyst and conductive intermediate layer to lower PGM loading without losing the catalyst surface area or conductivity.

porosity.^{24,25} A strategy to reduce PGM loading on PEMWE anodes has been the use of non-PGM cores such as TiO₂ with a shell of Ir catalysts (Ir-TiO₂) as illustrated in Figure 1b. However, in order to maintain conductivity of the shell, Ir loadings in excess of 50 wt % Ir are necessary,²⁶ as demonstrated for half-cell OER and electrolyzer performances.^{2,11,19,27,28}

We propose modifying the core–shell architecture by adding a very thin layer of conductive and electrochemically stable interfacial material, namely Pt or Au, between the TiO₂ core and the Ir catalyst (Figure 1c–e). Such conductive layers can also provide the possibility to further nanostructure the Ir catalyst and the conductive layer itself to reduce overall PGM loading without compromising specific activity, as depicted in Figure 1d,e. This strategy represents a new pathway to reduce Ir loading without compromising the activity and conductivity. Replacing Ir with Pt or Au has economic advantages as well in the short and medium terms, that is, until earth-abundant elements replace PGMs as OER catalysts. Pt and Au are a magnitude more abundant than Ir on the earth's crust.²⁹

Our inspiration comes from the use of Pt as a corrosion-resistant protective coating in PEMWE anode porous transport layers and bipolar plates, where they are known to withstand over 50,000 h of service.^{30–33} These precious metal-coated TiO₂ conductive catalyst supports (CCSs) also offer a pathway to enhance mass transport in the CLs by changing the TiO₂ particle size and thus improving the CL porosity. Akin to the roles carbon supports play in Pt/C CLs,³⁴ we advocate that the use of a substrate has the potential to increase the CL thickness, improve the distribution of Ir at low loadings, and renders an extra degree of flexibility in design by allowing for different Ir wt % on the support to be used. Generation of targeted materials interfaces at the nanoscale presents additional opportunities to engineer highly efficient and stable active sites.³⁵

In this paper, we synthesized CCS particles with thin layers of either Pt or Au nanoparticles prepared by a photochemical (PC) reduction deposition method (Table S1). As a control, CCSs were also synthesized using an incipient wetness impregnation (WI) method. In both systems, Ir was subsequently deposited on the CCSs using the WI method. Conductivities were measured using an in-house assembled DC conductivity setup,³⁶ and catalyst activities toward the oxygen evolution reaction (OER) were evaluated in a rotating disk electrode (RDE) and in a PEMWE. Throughout, we compare the performance with state-of-the-art commercial catalysts and previous investigations using supported Ir catalysts from the literature. We also correlate the activities with the physical characteristics of the catalysts using scanning and transmission electron microscopy (SEM and TEM), energy dispersive X-ray spectroscopy (EDS), X-ray photoelectron spectroscopy (XPS), and X-ray diffraction (XRD). Our findings provide rational pathways toward engineering more efficient and stable active sites at the support, conductive layer, and catalyst surfaces and interfaces.

EXPERIMENTAL SECTION

Photochemical Synthesis of CCS. A TiO₂ nanoparticles (<100 nm, 42–52 wt % in xylene, Sigma-Aldrich) slurry (5 mL) is added to 15 mL of deionized water (15 mL) in a centrifuge vial and vortexed. The suspension is centrifuged at 3500 rpm (700g) for 10 min before the supernatant is decanted and the precipitate is resuspended in deionized water

only the surface Ir atoms participating in catalysis. Currently, PEMWE anodes typically utilize unsupported Ir resulting in relatively large PGM catalyst particles and clusters on the order of 80 nm and larger that are applied at high loading (>1 mg_{Ir}/cm²) to maintain adequate CL thickness, connectivity, and

(20 mL). The centrifugation and washing are repeated 4 times. The final TiO_2 precipitate is dried under vacuum at 60 °C for 12 h. Dried TiO_2 nanoparticles (200 mg) are added to deionized water (50 mL) and combined with an appropriate mass of chloroplatinic or chloroauric acid (Fischer Scientific) to achieve 25 wt % metal on TiO_2 . The combined materials are stirred for 20 min to prepare a homogeneous mixture. The mixture is placed under a solar simulator equipped with a Xe lamp and AM1.5G filter, while stirring for 4 h to allow the deposition of gold or platinum nanoparticles onto the TiO_2 nanoparticle substrates (Supporting Video S1).³⁷ The solution is then centrifuged three times at 9000 rpm (7000g) for 15 min each. After each cycle, the supernatant is disposed of, and the 50 mL centrifuge vial was filled completely with deionized water and sonicated for 5 min before returning to the centrifuge.

Incipient Wetness Impregnation and Thermal Reduction Synthesis. An appropriate mass of dried TiO_2 nanoparticles is placed in a mortar and pestle. The exact mass of chlorometallic salts of Pt and Au is dissolved in acetone (2 mL, VWR Chemicals). Then, the chlorometallic salts are added dropwise to the TiO_2 powder while continuously grinding with the pestle. The resulting mixture is transferred to a quartz boat and placed in a tube furnace. The temperature is ramped to 400 °C at 10 °C/min under a reducing atmosphere (5% H_2 in Ar). After dwelling at 400 °C for 2 h, the temperature is allowed to naturally cool down to room temperature. On both the Au- and Pt-coated CCSs, 25 wt % Ir is deposited using the incipient wetness impregnation method as well as to prepare Ir-Pt/Au- TiO_2 -PC/WI catalysts. Therefore, PC and WI indicate the synthesis pathway for the deposition of the Pt and Au conductive layer onto TiO_2 , with Ir always deposited using WI on CCS.

Thermal Oxidation of CCS Supported Ir Catalysts. The catalysts are loaded on quartz boats and placed inside a furnace. The temperature is ramped at 10 °C/min to 400 °C under ambient conditions. The furnace temperature is kept at 400 °C for 2 h and then naturally allowed to cool down to room temperature.

Physical Measurements. XRD plots are recorded in Bragg–Brentano optics geometry with a Cu $K\alpha$ source on a Rigaku SmartLab instrument. SEM micrographs are obtained using a SEM FEI Quanta 250 FEG equipped with a Bruker Quantax 200 EDX detector. XRF measurements are carried out using a Bruker M4 Tornado Micro-XRF. STEM micrographs were acquired using a 200 kV FEI monochromated F20 UT Tecnai instrument. The TEM-EDX maps are collected on a FEI TitanX 60–300 microscope equipped with a Bruker windowless EDS detector with a solid angle of 0.7 steradians. XPS data are collected on a Kratos Axis Ultra DLD system at a takeoff angle of 0° relative to the surface normal at room temperature. A monochromatic Al $K\alpha$ source ($h\nu = 1486.6$ eV) is used to excite the core level electrons of the material. Pt 4f, Ir 4f, Ti 2p, C 1s, and O 1s core levels are collected, with a pass energy of 20 eV, step size of 0.05 eV, and 8 sweeps each to obtain a good signal-to-noise ratio. The survey spectra (Figure S1) are acquired with a pass energy of 160 eV, step size of 1 eV, and 3 sweeps. The measurements are performed at ultrahigh-vacuum conditions (7.5×10^{-9} Torr).

Conductivity Measurements. A homemade DC conductivity setup was used to measure the particle conductivity.³⁶ Briefly, the catalyst powder was sandwiched between copper electrodes and compressed to 200 lb/in², the thickness was

measured, and an I – V curve was generated from –50 to 50 mV using a potentiostat (SP300, BioLogic). The catalyst conductivity was extracted from the slope of the curve and the catalyst thickness.

Electrode Preparation. The electrochemical measurement system and methods are adapted from earlier reports.³⁸ The gold disk working electrode is prepared by polishing with a 0.05 μm alumina slurry. The disk is rinsed and bath sonicated for 30 s to remove residual slurry and impurities. The disk is rinsed again and dried via a compressed nitrogen air gun. The glassware is cleaned by rinsing in ultrapure water (18.2 M Ω , Milli-Q), boiling for 1 h, and rinsing again. Catalyst inks are coated as a thin film layer on a polished gold tip working electrode (5 mm diameter). To prepare the inks, catalyst powder (3.5 mg) is combined with water (7.6 mL), 2-propanol (2.4 mL, VWR), and Nafion solution (40 μL , 5 wt % in alcohol, Ion Power). The catalyst suspension was bath sonicated for 20 min. Ten μL of the well-dispersed catalyst ink was pipetted onto the gold disk surface of the working electrode as it rotated on an inverted RDE at 100 rpm to distribute the ink evenly. The RDE speed is increased to 700 rpm and allowed to dry for 15–20 min until it was completely dry.

Electrochemical Measurements (RDE). Electrochemical measurements are performed using a Pine Instrument RDE and SP-300 potentiostat from BioLogic Science Instruments. The activities are recorded in 0.1 M HClO_4 electrolyte at 25 °C. A gold wire and dynamic hydrogen electrode (DHE) are used as the counter and reference electrodes, respectively. All potentials are adjusted to RHE. Once set up, the system is purged with ultrahigh-purity Ar for 15 min before the working electrode is placed in the electrolyte, and the electrochemical measurements are recorded. Commercial supported baseline catalyst, Elyst Ir75 0480, IrO_2 - TiO_2 (75 wt % Ir) on TiO_2 , is purchased from Umicore.

The 50 preliminary cyclic voltammetry (CV) scans are recorded at a 500 mV/s between 0.025 and 1.5 V. An additional 3 CV scans are run at a rate of 20 mV/s between 0.025 and 1.0 V. The 50 conditioning CV cycles are then collected from 1.2 to 1.8 V at 100 mV/s and 2500 rpm. Five OER activity CVs are then recorded at 20 mV/s. The short-term stability of selected samples is evaluated at 1.8 V and 2500 rpm.

Membrane Electrode Assembly. The fabrication of the membrane electrode assembly (MEA), the cell integration and testing have been described elsewhere.³⁹ In brief, cathode half-cell catalyst-coated membranes using Nafion N117 (Ion Power) were prepared as described earlier on a Sono-Tek Exactcoat spray coater to achieve 0.3 mg/cm² Pt loading (45.6 wt % Pt/C, Tanaka). Carbon gas-diffusion layers with a microporous layer (29 BC, Sigracet) were used on the cathode. The spray coating is not suitable for TiO_2 supported anode catalysts, since the supported catalyst particles precipitate readily on the syringe, delivery tubes, and nozzle head.¹¹ Thus, a modified slot-die method was utilized.⁴⁰ In brief, 1 mL of water, catalyst, and Nafion (11.6 wt % of the catalyst) were added in a centrifuge tube and sonicated using a probe sonicator. The ink was then immediately cast on the N117 membrane secured in place over the vacuum hot plate of the Sono-Tek Exactcoat at 50 °C. The catalyst loading was determined using an in-house prepared calibration curve based on XRF intensity counts. Titanium porous transport layers (Proton OnSite/NEL) were used on the anode after wet

TEM image (g), high-resolution TEM (h) and Pt particle size distribution of 100 Pt nanoparticles (i) of Pt-TiO₂-PC. High-angle annular dark-field (HAADF) image (j) and EDS maps (k–m) of Ir-Pt-TiO₂-PC-ann. All scale bars in (a–f) are 0.5 μm and scale bars in (j–m) are 40 nm. EDS spectra corresponding to EDS maps above are in Figures S5 and S6.

proofing with 3.5% PTFE (DISP 30, Ion Power). Ten mil and 7 mil PTFE sheets (McMaster-Carr) were used to seal around the porous-transport and gas-diffusion layers, respectively.

Cell Testing. For the cell testing, liquid water at 80 °C was pumped on the anode side at 100 mL/min and N₂ at 200 sccm and 100% relative humidity on the cathode side. The cell temperature was monitored on the cathode end plate and the water temperature at the anode outlet. Chronopotentiometric (CA) steps were collected for 3 min from 25 to 5000 mA total current at various intervals after conditioning the cell at 80 °C for 1 h. Average potentials of the last 30 s were used to generate polarization curves. A multichannel potentiostat (VSP300) from BioLogic equipped with electrochemical impedance spectroscopy (EIS) and a 10 A booster was used for all electrochemical cell tests. EIS data were collected from 10 mHz to 200 kHz.

RESULTS AND DISCUSSIONS

Photoreductions of chlorometallic salts were used to prepare Au-TiO₂-PC and Pt-TiO₂-PC CCSs (Figure S2). Analogous materials were also prepared using the WI method followed by thermochemical reduction (M-TiO₂-WI) using the same precursor chemicals.⁴¹ Ir was deposited on all the M-TiO₂ materials using the WI method to generate Ir-(Au/Pt)-TiO₂ (PC/WI). The target deposition of each PGM metal on TiO₂ is 25 wt % except for the control Ir-TiO₂-WI, where we instead prepared 50 wt % Ir without the intermediate conductive layer (Table S1). The relative ratios of each element post-synthesis were determined using XRF (Figures S3 and S4). Irrespective of the precursor ratio or the irradiation duration, the Pt loading did not exceed 18 wt %, indicating that the photoreduction

synthesis method utilized here is self-terminating. To investigate the effects of thermal annealing on physical properties as well as electrocatalysis, the materials were annealed at 400 °C for 2 h. The thermally treated samples are designated as “ann” hereafter (Table S1).

To probe the uniformity and morphology of the prepared catalysts, SEM, TEM, and the corresponding EDS elemental maps were collected. The SEM (Figure 2a), corresponding EDS maps (Figure 2b,c), and EDS spectrum (Figure S5) show that Pt is uniformly deposited on the TiO₂ surface when the conductive Pt layer is deposited using the PC method. As apparent from the TEM image in Figure 2g,h, Pt nanoparticles, roughly 2–3 nm in size (Figure 2i), deposit evenly on the TiO₂ surface when Pt is deposited on TiO₂ using the PC method. Furthermore, the Pt nanoparticle distribution is maintained after Ir deposition and thermal annealing (Figure 2j–m and Figure S6). Conversely, a non-uniform Au distribution in Au-TiO₂-PC is observed (Figure S7), with some areas of homogeneous coverage (Figure S7). The EDS spectra for Au-TiO₂-PC in Figures S7 and S8 indicate lower loadings of Au when compared to the Pt EDS spectrum in Figure S5 even though the starting precursor ratio for both Au and Pt was 25 wt %.

Half-Cell Characterization. Using RDE, we probed the electrochemical activity of the CCS electrocatalysts with and without thermal treatment compared to the commercial baseline Umicore (IrO₂-TiO₂). The *i*R corrected OER activity in 0.1 M HClO₄ (Figure 3), gauged by onset potentials, was highest for Ir-Pt-TiO₂-PC > Ir-Au-TiO₂-PC > Umicore > Ir-TiO₂-WI, while the geometric current density at 1.8 V was highest for Ir-Au-TiO₂-PC > Ir-Pt-TiO₂-PC ~ Umicore > Ir-

Figure 3. OER activities (*iR* corrected) of Ir catalysts supported on TiO₂. (a) Activities normalized to a geometric surface area of the working electrode. (b) OER activities at 1.8 V normalized to mg of Ir. (c) CA plots at 1.8 V. (d) Tafel plots (dotted lines) with calculated Tafel slopes (mV/dec). The electrolyte is 0.1 M HClO₄, the working electrode disc and counter electrode wire are gold, and the reference electrode is a dihydrogen electrode. The working electrode is rotated at 2500 rpm, and the scan rate is 20 mV/s. Total catalyst loadings on the working electrodes are 3.49 μg_{Ir}/cm².

350 TiO₂-WI. Overall, annealing was shown to have a deleterious
 351 effect on Ir-Au-TiO₂-PC and Ir-TiO₂-WI; however, Ir-Pt-TiO₂-
 352 PC-ann retained a substantial amount of its activity even
 353 slightly exceeding the commercial Umicore IrO₂-TiO₂ catalyst.
 354 Retention of excellent activity after oxidation is critical for
 355 OER catalysts intended for PEMWE because they are
 356 employed in highly oxidizing electrochemical environments.
 357 CCSs without Ir deposition do not show significant OER
 358 activities as expected (Figure S9).

359 While geometric OER activity of Ir-Pt-TiO₂-PC and
 360 commercial Umicore catalyst are similar at 1.8 V (Figure
 361 3a), the benefit of employing a Pt conductive layer is
 362 demonstrated when the activities are normalized to an Ir
 363 mass loading (Figure 3b). At 1.8 V applied potential, Ir-Pt-
 364 TiO₂-PC generates 1.02 A/mg_{Ir} compared to 0.42 A/mg_{Ir}
 365 for the Umicore catalyst. This represents a 141% improvement in
 366 mass-normalized OER activity with a 42% lower PGM content
 367 (75 wt % Ir in Umicore catalyst vs 25 wt % Ir and 18 wt % Pt
 368 in Ir-Pt-TiO₂-PC). Even after thermal oxidation, the Ir-Pt-
 369 TiO₂-PC-ann catalyst generates 0.59 A/mg_{Ir} activity, that is, a
 370 39% improvement in Ir mass-normalized OER activity. The
 371 utility of a uniform and thermally stable conductive layer is also
 372 highlighted when Ir-Pt-TiO₂-PC is compared to Ir-Au-TiO₂-
 373 PC and Ir-TiO₂ catalysts; the OER activities of those two
 374 systems drop drastically upon thermal annealing. The mass
 375 normalized activities in Figure 3b are comparable to recently
 376 reported Ir catalysts supported on TiO₂ supports (Table S2).
 377 The mass normalized activities are still a magnitude lower than
 378 the state-of-the-art unsupported³⁸ and antimony-doped tin
 379 oxide supported Ir catalysts.⁹ However, activities of even the

commercial catalysts can vary widely depending on the ink
 preparation methods and electrochemical conditions. Each
 catalyst needs to be optimized for an ionomer to catalyst ratio,
 sonication/stirring/shearing, and other catalyst ink preparation
 parameters.³⁸

When the commercial catalysts and as-synthesized Pt-CCS
 supported materials are subjected to chronoamperometry
 (CA) at 1.8 V to assess initial performance, it is observed
 that the commercial Umicore catalyst initially generates higher
 geometric OER activities, but the activities converge within 5
 h. Critically, the synthesized Ir-Pt-TiO₂-PC catalysts generate a
 similar activity after 5 h of CA to the commercial catalyst while
 containing 33% less PGM loading. When the as-prepared and
 annealed Ir-Pt-TiO₂-PC catalysts are compared (Figure 3c),
 the activity of as-prepared catalyst is significantly higher
 initially but drops precipitously to reflect that of the annealed
 catalyst within 30 min. The Ir-Au-TiO₂-PC catalyst, initially,
 also shows the highest activity at 1.8 V applied potential, but
 becomes inactive within minutes. Longer-term stability studies
 including online catalyst dissolution measurements and
 operando characterization of electrocatalysts are deemed
 beyond the scope of the current investigations.

From the Tafel slopes in Figure 3d, it is apparent that the
 commercial catalyst (Umicore) and as-synthesized Ir-TiO₂-WI
 and Ir-Au-TiO₂-PC exhibit faster OER kinetics (65 mV/dec)
 in comparison to Pt-containing CCS supported catalysts (81–
 190 mV/dec). Annealed Ir-TiO₂ and Ir-Au-TiO₂ are not
 included in the Tafel analysis since the activity is negligible in
 the relevant potential window (Figure 3a). The Tafel slopes of
 Pt-containing CCS supported catalysts intriguingly show two

distinct regions. At low overpotentials (<250 mV), both as-synthesized and annealed Ir-Pt-TiO₂ catalysts show high Tafel slopes (>148 mV/dec), indicating slow kinetics but low onset potentials. At higher overpotentials (>250 mV), faster kinetics (81 mV/dec) predominate OER activity. Previous investigations on Ir and Ru via experimental and theoretical analysis have ascribed the “kink in Tafel slopes” to either different active sites or catalyst surface reorganization at different applied potentials.^{42,43} These results may also indicate that the presence of the interfacial layer modulates the catalyst active site. Generally, lower Tafel slopes indicate faster kinetics and better electrochemical performance. Our observations here indicate that other effects may be affecting overall performance more dominantly than those encompassed in Tafel slopes. Further optimizations to enhance the OER kinetics coupled with the low onset potentials hold significant promise to boost overall activity of low Ir-loading CLs using supported catalysts.

Structure–Activity Relationships. In order to rationalize the trends in electrochemical activity and to understand the structure–activity relationships, we thoroughly characterized the catalysts for electronic conductivity, crystallinity, and surface composition. Conductivities of the prepared catalysts (Figure 4) show that the presence of Pt conductive layer is

Figure 4. Electronic conductivities of various catalysts supported on TiO₂. Umicore is the commercial IrO₂-TiO₂ catalyst, and “ann” represents thermally annealed materials.

responsible for maintaining a relatively high conductivity during thermal annealing. The conductivities are similar to previous reports on various supported IrO_x catalysts prepared using the Adams fusion method (Table S4).^{26,44,45} As synthesized, the Ir-TiO₂-WI, Ir-Pt-TiO₂-PC, and Ir-Au-TiO₂-PC have similar conductivities (37–44 S/cm). However, upon annealing, the conductivities of Ir-TiO₂-WI-ann and Ir-Au-TiO₂-PC-ann decrease dramatically to 6 and 18 S/cm, respectively, but the conductivity of Ir-Pt-TiO₂-PC-ann slightly improves to 44 S/cm. The observations may indicate that Ir and Au agglomerate rapidly under thermal annealing conditions (Figure S7), and they are weakly adsorbed on the TiO₂ surface. This leads to the dramatic OER activity reduction observed in Figure 3a,b. Pt however is strongly bound to the TiO₂ surface, retains conformal homogeneous distribution (Figure 2), and maintains a relatively high OER activity post-annealing.

XRD was used to investigate the crystallinity of the CCSs and catalysts. For the synthesized Pt-TiO₂-PC CCSs (Figure 5a), only TiO₂ peaks are visible in the XRD, suggesting that the PC deposition method leads to the synthesis of either an

amorphous Pt layer or extremely small Pt nanoparticles. This is in agreement with the observed 2–3 nm crystalline Pt nanoparticles (Figure 2). Conversely, for the Pt-TiO₂-WI, the Pt peaks such as the Pt (111) at 39.6° are apparent. When Ir is deposited to prepare Ir-Pt-TiO₂-PC, peaks corresponding to Ir and TiO₂ are observed, but the Pt peaks remain absent. These observations indicate that Pt deposited on TiO₂ via the PC method does not aggregate under thermochemical reduction conditions during Ir deposition via the WI method to prepare Ir-Pt-TiO₂-PC. Unlike the Pt-TiO₂-WI and Ir-Pt-TiO₂-WI systems where the Pt (111) peak at 39.6° is apparent, the peak is absent for both Pt-TiO₂-PC and Ir-Pt-TiO₂-PC.

Conversely to the Pt CCSs, the XRD peaks for Au are prominent irrespective of the synthesis method (Figure 5b). The Au (111) peak at 38.1° is wider and less prominent in Ir-Au-TiO₂-PC than in Ir-Au-TiO₂-WI, indicating that the Au crystallite sizes are smaller from the PC method than from the WI method. However, as determined by electron microscopy (Figure S7) and visual observations, the Au precursor is photosensitive, and some portion of it is readily reduced upon exposure to ambient light without semiconductor-assisted photoreduction. It is likely that the Au peaks in Ir-Au-TiO₂-PC are from the initial precipitation rather than PC reduction on TiO₂ surface. However, akin to Ir-Pt-TiO₂-PC, the Au peaks in Au-TiO₂-PC do not show significant aggregation or crystallite size coarsening during the Ir deposition via the WI method.

Curiously, Ir-Pt-TiO₂-PC does not show Pt or Ir oxidation during thermal treatment, as apparent from Figure 5c, with no significant peaks corresponding to iridium oxides (IrO_x) or platinum oxides (PtO_x). However, the Au and Ir are oxidized to Au₂O₃ and IrO₂ for Ir-Au-TiO₂-PC-ann. The observations indicate that the Pt interlayer may have a stabilizing effect on Ir with respect to oxidation, and the bulk of Pt itself does not oxidize. The oxidation and aggregation lead to both conductivity reduction (Figure 4) and activity loss (Figure 3) for Ir-TiO₂-WI and Ir-Au-TiO₂-PC-ann, but Ir-Pt-TiO₂-PC is thermally stable and maintains high conductivity and activity. Particle size analysis shows that crystallite sizes generally increase upon annealing (Table S3). The Pt CCS supported Ir crystallite size increases from 10 to 28 nm, while the crystallite size of the commercial supported Ir catalyst is 9 nm. Thus, some of the activity loss can be attributed to agglomeration and loss in the active surface area.

Collectively, the XRD (Figure 5), microscopy (Figure 2), and electrochemical activity trends (Figure 3) also point to a subtle difference in how Au and Pt reductions and depositions may proceed. By the eye, the Au precursor decomposes rapidly when exposed to ambient light, forming a precipitate. However, the slow evolution of color (darkening) during PC irradiation indicates that some Au precursor remains in the solution and is reduced at a much slower rate to metallic Au nanoparticles under PC irradiation (Figure S2). These Au nanoparticles agglomerate during the Ir deposition via the WI method to prepare Ir-Au-TiO₂-PC and thermal treatment to generate Ir-Au-TiO₂-PC-ann. We chose not to employ strategies such as the use of surfactants or dilute precursors to prevent Au nanoparticle formation and aggregation due to the associated complications with post-synthesis purification steps. The Pt deposition in contrast occurs by photoreduction at the TiO₂ surface, that is, semiconductor-assisted photo-driven reduction to form Pt-TiO₂-PC. The process thus leads to Pt nanoparticles evenly distributed on a TiO₂ surface, and strong adsorption to the substrate prevents Pt nanoparticle

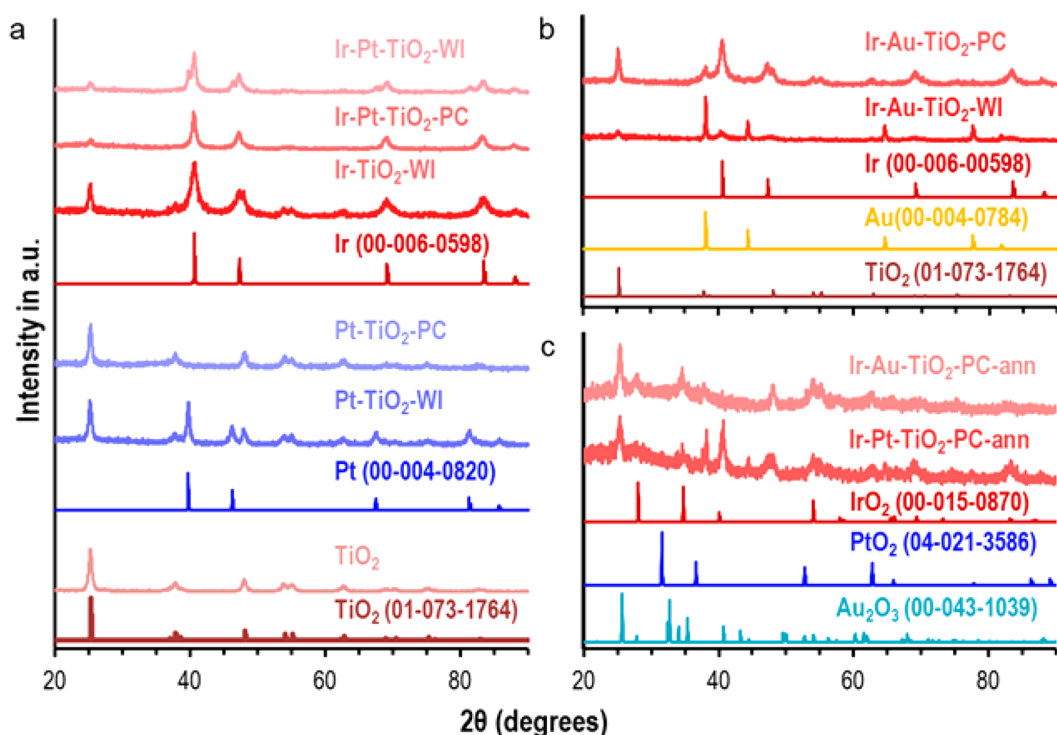

Figure 5. XRD diffraction patterns for: (a) Pt coated CCSs (blue) and Ir supported on CCSs (red). (b) Ir supported on Au coated CCSs and (c) effects of thermal annealing in air for Ir deposited on CCSs synthesized via PC reduction. Diffraction pattern of as-obtained TiO_2 nanoparticles (TiO_2) is included in (a), and all the reference patterns are accompanied by corresponding PDF numbers.

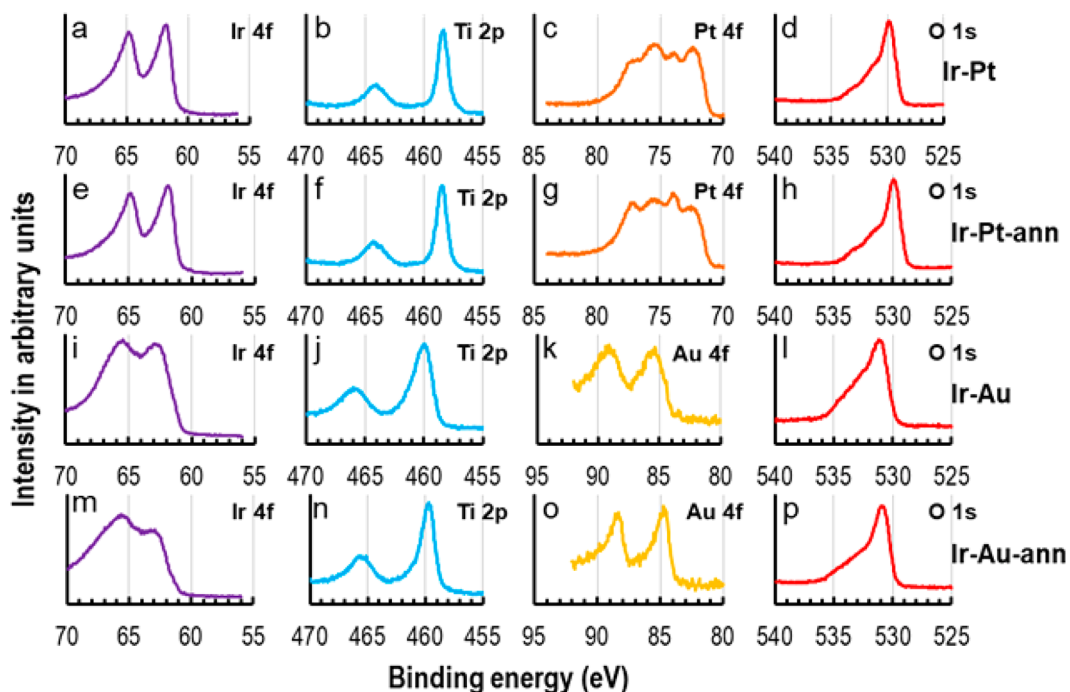

Figure 6. XPS spectra of Ir catalysts supported on CCSs synthesized using a photochemical reduction method. (a–d) Ir-Pt- TiO_2 -PC, (e–h) Ir-Pt- TiO_2 -PC-ann, (i–l) Ir-Au- TiO_2 -PC, and (m–p) Ir-Au- TiO_2 -PC-ann. The spectra are as collected without background correction.

aggregation during WI reduction to prepare Ir-Pt- TiO_2 -PC and thermal treatment steps to prepare Ir-Pt- TiO_2 -PC-ann.

By XPS (Figure 6), it is apparent that the majority of the near surface Ir deposited on Pt CCSs is IrO_2 with some metallic (Ir^0) characteristic, apparent from the core Ir 4f binding energies (i.e., Ir $4f_{7/2}$ at 61.9 eV and Ir $4f_{5/2}$ at 64.9 eV,

respectively).^{46,47} The XPS spectrum for Ir-Pt- TiO_2 -PC does not change before and after annealing in air, as apparent from the Ir 4f region (Figure 6a,e). There is, however, an increased level of Ir oxidation after annealing for Ir-Au- TiO_2 -PC, as apparent from the change in Ir 4f spectra in Figure 6i,m.⁴⁸ For the Ir deposited on Au CCSs (Figure 6i,m) and bare TiO_2

Figure 7. (a) Electrolyzer polarization curves using annealed Ir-Pt-TiO₂ and commercial Umicore catalysts at 1.0 mg/cm² PGM on the anode, 0.3 mg/cm² Pt (Pt/C) on the cathode, and liquid water feeds at 80 °C and N117 membranes. (b) Tafel plots of *iR* free polarization curves with the corresponding equations in the kinetics region.

(Figure S10), the Ir is mostly oxidized (IrO₂) with Ir 4f_{7/2} at 63 eV and Ir 4f_{5/2} at 66 eV. In agreement with the XRD (Figure 5c), XPS confirms that Ir deposited on Pt CCS is more metallic in nature relative to Ir deposited on Au CCS. Furthermore, the Ti 2p peaks are at lower binding energies for Ir-Pt-TiO₂-PC before and after annealing (Figure 6b,f), in comparison to, both, Ir-Au-TiO₂-PC (Figure 6j,n), and for Ir-TiO₂ (Figure S10). Similarly, the O 1s peaks for Ir-Pt-TiO₂-PC also appear at about 1 eV lower than that of Ir-Au-TiO₂-PC and Ir-TiO₂-WI. However, there is a significant change in the Pt 4f spectrum for Ir-Pt-TiO₂-PC. There is an increase in Pt²⁺ (74 eV) with respect to Pt⁰ (72 eV) after annealing.⁴⁹ Au 4f peaks show a slight shift to lower binding energy upon annealing as the full width at half-maximum gets smaller (Figure 6k,o).

The difference in the minima between the Ir 4f peaks in Figure 6i for Ir-Au-TiO₂ compared to that of Ir-Pt-TiO₂ (Figure 6a) has previously been rationalized as the interference from the Ti 3s peak by Aguilar-Tapia et al.⁵⁰ From the comparison of the XPS spectra, it is evident that the direct interaction between Ir and TiO₂ leads to higher binding energy shifts for Ir and Ti, while an interlayer of Pt prevents Ir and Ti from influencing each other's binding energies. The observations from XPS further confirm that Au does not form a uniform layer on TiO₂ to act as an interlayer between Ir and TiO₂. Ir-Au-TiO₂-PC behaves more akin to Ir-TiO₂ than Ir-Pt-TiO₂-PC during thermal annealing. Additionally, there is evidence of a charge transfer from Ir to Pt, which leads to Pt itself oxidizing during annealing (Figure 6c,g) and consequently Ir retaining a metallic character.^{46,51} In agreement with previous studies of Au-IrO₂ composites, Au on the contrary leads to increased Ir oxidation since the binding energies of Au 4f peaks shift slightly lower.⁵² The stability of the Ir surfaces deposited on Pt-CCSs evidenced from XPS spectra in Figure 6 directly correlate to the retention of high OER activities in Figure 3. Furthermore, the drastic loss in the OER activities of Au-CCS and TiO₂ supported Ir upon thermal annealing highlights the utility of using a stable conformal conductive layer between the OER Ir catalysts and the non-PGM TiO₂ cores.

PEMWE Performance. As a preliminary proof-of-concept demonstration for catalyst integration into a MEA, the most promising CCS catalyst (Ir-Pt-TiO₂-PC-ann) was integrated

into a PEMWE cell with 1.0 mg/cm² PGM loadings on the anode and 0.3 mg/cm² Pt (Pt/C) on the cathode and compared with the commercial TiO₂ supported Umicore catalyst at the same anode catalyst loadings. The balance of cell components, the membrane, the pretreatment conditions, and the testing conditions are described elsewhere.³⁹ From the polarization curves at 80 °C in Figure 7a, it is apparent that the Ir-Pt-TiO₂-PC-ann catalyst outperforms the commercial Umicore catalyst. It must also be emphasized that the CCS supported catalysts are yet to be optimized for CL integration and MEA performance, which is beyond the scope of this work. Additionally, it is also well established that each OER Ir catalyst requires a unique set of catalyst ink preparation and catalyst layer fabrication methods to perform optimally.⁵³ Nevertheless, the CCS supported catalysts outperform previously reported TiO₂ supported Ir catalysts assessed under similar testing conditions after optimization (Table S4).^{25,54,55} However, as with half-cell activities, the MEA performances are still significantly inferior to state-of-the-art unsupported IrO_x catalysts (Table S5).¹⁵ Ir-Pt-TiO₂-PC-ann achieves 1 A/cm² activity at 1.87 V, while the Umicore catalyst requires 1.89 V.

High-frequency resistances (HFRs), which account for ohmic losses of the entire cell, were used to generate *iR*-corrected polarization curves in Figure 7a.⁵⁶ The Tafel analysis in Figure 7b indicates that the OER kinetics of Ir-Pt-TiO₂-PC are superior (108 mV/dec) to the Umicore catalyst (120 mV/dec). The trend is in contrast to half-cell observations in Figure 3d, which showed lower Tafel slopes for Umicore catalysts (65 mV/dec) than for Ir-Pt-TiO₂-PC (81 mV/dec). The observation re-emphasizes that RDE performances are not always translatable to cell performance. The HFR-corrected polarization curves (Figure 7a) also allow a MEA performance comparison among various membrane thicknesses. From Table S5, it is apparent that the CCS supported catalysts generate comparable activities to other oxide supported IrO_x catalysts at 1 A/cm² under similar conditions and cell configuration. As with the half-cell analysis in Figure 3 however, further optimizations in catalyst structure, ink composition, and catalyst integration methods are necessary to match the performances of the state-of-the-art catalysts and catalyst layers.

CL thickness and porosity also influence the performance by improving transport. Cross-sectional SEM of the MEA illustrates that the CL thickness increased and the porosity was manipulated by employing CCS supports (Figure S11). The anode CL thickness is comparable to previous reports using 2–3 mg/cm² PGM catalyst loadings.^{22,40,54,57–59} Further investigations are underway to understand the contributions of the kinetics, mass transport, catalyst layer fabrication methods, and catalyst ink compositions in electrolyzer performance using CCS integrated CLs.

CONCLUSIONS

We have demonstrated a facile photoreduction method to generate a conformal layer of platinum nanoparticles on TiO₂, forming conductive layer coated supports (CCSs). The conductive intermediate layer prevents bulk iridium oxidation in the Ir-Pt-TiO₂ catalyst during annealing and improves the composite electrocatalyst conductivity at a significantly lower precious group metal (PGM) loading (39 wt %) in comparison to a TiO₂ supported commercial catalyst with 75 wt % PGM loading. Photoreduction generated a conformal platinum layer that is strongly bound to the semiconductor surface and is stable in thermochemical and electrochemical environments. The presented X-ray photoelectron spectroscopy, X-ray diffraction, and electron microscopy images show significant opportunities to further engineer highly active and stable surfaces, interfaces, and active sites utilizing the conductive interlayer in comparison to bare TiO₂ supports. The half-cell oxygen evolution reaction (OER) activities show that the Pt-CCS supported iridium generates a 141% higher OER mass activity than the commercial TiO₂ supported catalyst from Umicore. Furthermore, the single-cell performance of the CCS supported catalyst reveals a superior performance to other supported catalysts reported thus far, even prior to any integration and fabrication optimizations. Our investigations also reaffirm that translating the half-cell catalyst performance to device level performance requires considerable optimization during the catalyst layer fabrication and device integration. We expect future investigations utilizing CCSs to improve the electrolyzer performance significantly from CCS supported materials and device optimization via synthetic modifications as well as targeted catalyst ink preparation for each catalyst and cell fabrication methodologies.
