1 Abstract

Purpose: To examine responses to a simulated rugby league protocol designed
to include more stochastic commands, and therefore require greater vigilance,
than traditional team sport simulation protocols.

5 Methods: Eleven male university rugby players completed two trials 6 (randomised and control) of a rugby league movement simulation protocol, 7 separated by 7-10 days. The control trial (CON) consisted of 48 repeated ~115 8 s cycles of activity. The stochastic simulation (STOCH) was matched for the 9 number and types of activity performed every 5.45 min in CON, but included 10 no repeated cycles of activity. Movement using GPS, heart rate, RPE and Stroop test performance were assessed throughout. MVC peak torque, 11 12 voluntary activation (%) and global task load were assessed after exercise.

13 Results: The mean mental demand of STOCH was higher than CON (Effect 14 size (ES) = 0.56; ± 0.69). Mean sprint speed was higher in STOCH (22.5 ± 1.4 vs. 21.6 ± 1.6 km·h⁻¹; ES = 0.50; ± 0.55), which was accompanied by a higher 15 RPE $(14.3 \pm 1.0 \text{ vs. } 13.0 \pm 1.4; \text{ ES} = 0.87; \pm 0.67)$ and a greater number of 16 17 errors in the Stroop Test (10.3 \pm 2.5 vs. 9.3 \pm 1.4 errors; ES = 0.65; \pm 0.83). MVC peak torque (CON = -48.4 ± 31.6 N·m, STOCH = -39.6 ± 36.6 N·m) and 18 voluntary activation (CON = $-8.3 \pm 4.8\%$, STOCH = $-6.0 \pm 4.1\%$) was similarly 19 20 reduced in both trials.

Conclusions: Providing more stochastic commands, which requires greater vigilance, might alter performance and associated physiological, perceptual and cognitive responses to team sport simulations.

27 Introduction

37

66

76

28 The use of team sport match simulation protocols in sports science research is 29 now common. These protocols seek to negate the large variation (~15%) in 30 running distance and intensity observed between matches,¹ which might 31 otherwise mask meaningful changes in performance owing to an intervention. 32 Furthermore, physiological and perceptual responses can be measured 33 regularly in a controlled environment, which would not be feasible in competition. Accordingly, in rugby league, various iterations of the Rugby 34 35 League Movement Simulation Protocol (RLMSP) have successfully been used to examine changes in performance.^{2,3,4} 36

One aspect of competitive rugby league match play, which has often been 38 39 excluded from simulation protocols, is the stochastic nature of performance. 40 For example, the current interchange rugby league simulation protocol comprises repeated cycles of activity (115 s) lasting 46 min.⁵ The use of short 41 repeated cycles is common in team sport simulation protocols,^{6,7,8} with few 42 exceptions,⁹ which is likely an attempt to maintain the consistency of 43 performance in such activities.⁵ However, preserving high internal validity and 44 45 associated reliability might compromise the external validity of such 46 protocols.³ 47

48 The predictable and repetitive nature of current protocols compared to the 49 stochastic nature of match play, which requires decisions to be made based on 50 information retrieved from a dynamic environment, might influence exercise 51 performance and associated physiological and perceptual responses in several 52 ways. For example, with sustained vigilance during a repetitive activity, a 53 'zoning out' might occur causing disengagement from the task.¹⁰ Task disengagement and reduced vigilance negatively affects decision making,¹⁰ 54 55 whilst maintaining vigilance is associated with a greater 'mental demand' (i.e. 56 the amount of mental and perceptual activity required to complete a task, 57 including thinking, deciding, calculating, and remembering).¹¹ Mentally demanding tasks not only cause mental fatigue after a rugby match,¹² but can 58 also affect perceived exertion¹³ and running performance.¹⁴ Vigilance and 59 associated task engagement might also cause an altered attentional focus,¹⁰ 60 which can alter perceived exertion¹³ and performance.¹⁵ Finally, the predictable 61 62 nature of existing simulation protocols might result in a different pacing strategy to that observed in matches,^{2,16} where players must regulate their 63 exercise intensity whilst preserving the capacity to perform unpredictable 64 65 periods of exercise at an intensity greater than the match average.¹⁶

To the best of our knowledge, the effects of a stochastic order of activity during 67 simulated match play, compared to a conventional simulation comprising 68 repeated cycles, are currently unknown. It is important to understand the extent 69 70 to which making the required activity less predictable, and therefore increasing 71 the requirement for vigilance, might alter an individual's response to such 72 protocols if they are to be used in practice. Therefore, the purpose of the study 73 was to investigate the effects of a stochastic order of activity on performance 74 in, and physiological and perceptual responses to, the Rugby League 75 Movement Simulation Protocol for Interchange Players (RLMSP-i).

77 Methods

78 79

91

Participants

80 Eleven male university rugby players (league and union; age = 21.2 ± 2.0 y, body mass = 80.5 ± 6.4 kg, stature = 1.80 ± 0.10 m, predicted maximal oxygen 81 uptake $[VO_{2max}] = 50.8 \pm 3.8 \text{ ml} \text{kg}^{-1} \text{min}^{-1}$ completed the experiment. A priori 82 83 calculations showed that a sample of at least 10 participants was required, ¹⁷ based on a smallest worthwhile change (Cohen's d = 0.2) of 0.23 km·h⁻¹ for 84 sprint performance and a typical error of 0.28 km·h-¹ taken from an in-house 85 reliability study. Participants provided written informed consent and completed 86 87 a pre-test health questionnaire. Ethics approval was granted by the Faculty of Medicine, Dentistry and Life Sciences Research Ethics Committee, University 88 89 of Chester (1011-15-TM-SES). 90

Design

92 After an initial baseline visit to predict VO_{2max} (using a progressive shuttle run test)¹⁸ and habituate participants with all of the experimental procedures, each 93 participant completed two trials of RLMSP-i,⁵ separated by 7-10 days, in a 94 95 randomised cross-over design. Trials were completed at the same time of day 96 $(\pm 2 h)$ and differed in that either the standard protocol (CON), or a protocol 97 with a more stochastic series of commands (STOCH), was used. Participants 98 were instructed to refrain from strenuous activity and avoid caffeine and 99 alcohol in the 24 h before each trial. A self-reported food diary was recorded for the 48 hours immediately before trial one and replicated in the 48 hours 100 101 before trial two. Participants began each trial in a similarly hydrated state (preexercise urine osmolality for CON = 615 ± 292 mOsmol·kg⁻¹ and STOCH = 102 103 $621 \pm 303 \text{ mOsmol} \cdot \text{kg}^{-1}$). 104

105 Procedures

106 In the two trials, participants performed a standardised 10 min warm-up before 107 performing the RLMSP-i on an artificial synthetic grass surface. Participants ran alone, following the instruction of an audio signal that dictated the speed 108 109 and type of movement between various coloured cones. The RLMSP-i lasted 110 46 min, comprising two 23 min bouts separated by 20 min passive recovery. The CON trial comprised 24 repeated ~115 s cycles of activity.⁵ In the STOCH 111 112 protocol, the order of events was re-ordered to be non-cyclical and less 113 predictable (but was the same for every participant), with no repeated 'cycles'. 114 In an attempt to guarantee high and low-intensity actions were not 'bunched' 115 in the STOCH protocol, we ensured that the number and type of each movement were identical for both protocols within each quartile of each bout 116 117 (i.e. every 5.45 min; see Waldron et al.⁵). For example, this resulted in a range 118 of 36.6 to 136 s between 20.5 m sprints in CON and between 26.83 to 95.19 s 119 in STOCH. In both CON and STOCH, the required movements were dictated 120 via a pre-recorded audio signal played through a sound system. 121

122Throughout the RLMSP-i, participants were fitted with a GPS unit positioned123between the scapulae (10 Hz MinimaxX S5, firmware 6.75, Catapult124Innovations, Melbourne, Australia). The satellites available and horizontal125dilution of precision (HDOP) for all testing visits ranged from 12 – 17 and 0.5126- 1.5 AU, respectively. Participants' heart rate (HR) was collected throughout

127 the RLMSP-i using a HR monitor (Polar Electro Oy, Kempele, Finland) 128 wirelessly connected to the GPS. GPS data were analysed for speed (m·min⁻¹), 129 low (<14 km·h⁻¹) and high speed running (> 14 km·h⁻¹), peak speed, sprint to 130 contact speed, PlayerLoadTM (AU) and time at high metabolic power >20 W·kg⁻¹ 131 ¹ (s). In a separate in-house investigation, using a sample of n = 20 university 132 rugby players, the inter-day coefficient of variation (CV %) was determined 133 for each movement variable and ranged from 1.4 – 6.5%.

134

148

135 Blood was analysed for lactate concentration (B[La]; Lactate Pro, Arkray, 136 Japan) from a fingertip capillary sample 5 min before and immediately after 137 the first and second bout of the RLMSP-i (typical error = 1.15 mmol¹⁻¹). 138 Participants' rating of perceived exertion (RPE, 6-20 scale; Borg, 1985) was 139 recorded every quartile (5.45 min) of the first and second bout during each trial. 140 A global RPE for the session (sRPE, 0-10 scale) was recorded within 20 min of completing each trial. Cognitive function was assessed using a commercially 141 available Stroop Test application on a tablet computer (EncephalApp Stroop)¹⁹ 142 143 5 min before and immediately after the first and second bouts of the RLMSPi, which required participants to react 80 times as quickly as possible by 144 touching the corresponding colour at the bottom of the screen to various 145 coloured words (red, blue and green). Typical error of measurement was 146 147 calculated as 5.56 s and 1.65 for Stroop test time and errors, respectively.

149 Isometric force and voluntary activation of the knee extensors in the dominant 150 leg were measured using a dynamometer before and 15 min after the RLMSP-151 i (Biodex 3, Biodex Medical Sytems, Shirley, NY, USA). Participants sat in an upright position with 90° flexion in the hip and knee; straps were tightly 152 153 secured across the thorax and hip to minimise extraneous body movements 154 from the dynamometer. Participants performed four MVCs (each 4 s duration) 155 with 2 min rest between efforts. Force output was A/D converted at a sampling 156 frequency of 1,000 Hz (AcqKnowledge III, Biopac Systems, Massachusetts). Transcutaneous electrical stimulation of the quadriceps muscle was delivered 157 using a constant-current stimulator (Digitimer DS7, Hertfordshire, UK) to 158 159 determine voluntary activation. Two rectangle self-adhesive surface electrodes 160 $(5 \times 13 \text{ cm}; \text{Axelgaard Manufacturing Co. Ltd., Lystrup, Denmark)}$ were applied distally and proximally across the knee extensors. The outline of both 161 162 electrodes was drawn on to the skin using a permanent marker to minimise 163 variability of electrode placement between sessions. Paired electrical stimuli 164 (100 Hz; at 20% above the amperage required for pre-determined peak twitch torque) were delivered to the relaxed muscle pre-contraction (control twitch), 165 and 3 s into the MVC (superimposed twitch). Voluntary activation (VA%) was 166 calculated as a ratio of the superimposed twitch relative to the twitch response 167 of the relaxed muscle (1- [superimposed twitch/control twitch] $\times 100$). Peak 168 169 MVC from the 4 contractions was calculated as the mean torque 50 ms before 170 the superimposed stimulation delivery. In-house typical error of measurement 171 was 10.8 N·m and 1.64 % for MVC and VA%, respectively. 172

Subjective task load was measured ~20 min after each trial of the RLMSP-i
using the National Aeronautics and Space Administration Task Load Index
(NASA-TLX). Participants rated six subscales of task load (mental demand,
physical demand, temporal demand, frustration, effort, and performance). Each

177 subscale was presented as a 10 cm line with visual anchors at either end (e.g. 178 low/high), corresponding to an unseen numerical scale from 0-100 AU. A 179 weighted scoring of the six subscales was ascertained using 15 pairwise 180 comparisons between each subscale (e.g. mental demand vs. effort). Participants were instructed to circle the descriptor that represents the most 181 182 important contributor to task load during the RLMSP-i. The weighted score 183 corresponded to the number of times each subscale is selected as being the most important contributor to global task load. A task load (weighted rating) score 184 185 was then calculated by multiplying the weighted score by the rated score for 186 each individual subscale.

188 Statistical Analysis

187

189 All data are reported as means \pm SD. Changes in dependent variables were 190 analysed using effect sizes and 95% confidence intervals (ES; ±confidence 191 interval). In using this approach, the reader can interpret our results in terms of 192 traditional statistical significance should they wish to (i.e. if our confidence 193 interval crosses 0, then $P \ge 0.05$), or as a 'compatibility interval' (i.e. the range 194 of values compatible with our data that would not be deemed different to our 195 observed effect at the 0.05 level). We interpreted our data based on the 196 magnitude of the observed change between trials, calculated as the mean 197 difference between trials divided by the pooled SD of trials, and considered as: 198 small ≥ 0.2 , moderate ≥ 0.6 and large ≥ 1.2 . We considered a substantial effect 199 to be any ES \ge 0.2 or \le -0.2, with a confidence interval that did not cross *both* ES -0.2 and 0.2. Effects were considered to be unclear when the 95% 200 201 confidence interval crossed both substantially positive and negative effects. 202 The above calculations were completed using a predesigned spreadsheet.¹⁷

Results

205 The mean speed was higher during the STOCH trial over the entire simulation. Differences between trials were unclear for low intensity distance, high 206 intensity distance, sprint to contact speed, PlayerLoadTM and high metabolic 207 power (see Table 1). Similarly, differences between trials across bout quartiles 208 209 for speed, high speed running and sprint to contact speed across the protocol 210 were generally unclear (Figure 1A, B and C). However, for mean sprint speed (that is, the mean of the peak speed attained in each sprint), there was a mean 211 212 increase in the STOCH trial compared to the CON across all quartiles of the 213 protocol (Figure 1D).

214 215 216

217 218

203 204

************Insert Figure 1 about here*********

219Physiological and perceptual responses to the trials are shown in Table 2.220Unclear differences were observed between trials in % HR_{max} across the entire221protocol (ES = 0.15; ± 0.38). After the first and second bout, blood lactate222concentration increased less after the STOCH compared to the CON trial.223Participants reported higher average RPE (ES = 0.87; ± 0.67) and sRPE (ES =2240.52; ± 0.60) after the STOCH protocol.

225 226

***********Insert Table 2 about here********

| 227 | |
|-----|---|
| 228 | The reduction in isometric knee-extensor torque after exercise was small for |
| 229 | the CON (-48.4 \pm 31.6 N·m, ES = 0.56; \pm 0.25) and STOCH (-39.6 \pm 36.6 N·m, |
| 230 | $ES = 0.48; \pm 0.30$). Accordingly, the difference in post-exercise knee extensor |
| 231 | peak torque between trials was unclear (CON = 282.7 ± 80.7 N·m, STOCH = |
| 232 | 279.0 ± 66.7 N·m; ES = 0.04; ± 0.19). Voluntary activation (VA%) decreased |
| 233 | after exercise in both the CON (-8.3 \pm 4.8%; ES = 0.95; \pm 0.68) and STOCH (- |
| 234 | $6.0 \pm 4.1\%$; ES = 1.23; ±1.04) protocols (Table 2). |
| 235 | |
| 236 | The time taken to complete the Stroop test after STOCH (75.0 \pm 4.3 s) was |
| 237 | higher than CON $(72.2 \pm 4.3 \text{ s})$ (ES = 0.59; ±0.62). The total number of |
| 238 | attempts required to complete the task was higher (ES = 0.65 ; ± 0.83) after the |
| 239 | STOCH (10.3 \pm 2.5) compared to the CON trial (9.3 \pm 1.4; Table 3). |

| 250 | |
| 251 | Discussion |
| 252 | This is the first study to seek to manipulate and quantify the mental demands |
| 253 | associated with simulated rugby activity. Our data shows that having more |
| 254 | unpredictable movement commands than those traditionally used in team sport |
| 255 | simulations might result in a small increase in how mentally demanding the |
| 256 | exercise is perceived to be. This would be consistent with observations that |
| 257 | repetitive ²⁰ and learnable actions ²¹ necessitating less vigilance require fewer |
| 258 | attentional resources and result in lower mental fatigue. ²² As such, the |
| 259 | unpredictable order of events employed in the STOCH trial might have |
| 260 | increased vigilance requirements for participants to respond correctly to the |
| 261 | upcoming audio command. Greater mental demands also occur when |
| 262 | uncertainty of a signal's origin (in this case the nature of the command) is |
| 263 | increased, ²² which results in a greater 'vigilance decrement' (i.e. a decrement |
| 264 | in information processing and resulting cognitive performance) The |

information processing and resulting cognitive performance). The 264 265 observation here that elements of Stroop test performance were worse in the STOCH trial would support such a notion. Given that we observed a small 266 effect with confidence intervals that incorporate zero, we encourage other 267 researchers to examine the vigilance requirements of team sport simulations to 268 determine whether mental demands are indeed affected. Future studies might 269 270 also explore whether cognitive function that more closely replicates match-like 271 actions (e.g. decision making for skill execution) is influenced by the degree of 272 mental demand associated with simulated match activity.

RPE is a key determinant of performance and fatigue in team sports such as
 rugby.³ The potentially higher mental demand associated with the modified
 RLMSP-i might explain the observed increase in state and session RPE in the

273

STOCH trial. RPE is informed by numerous afferent and efferent factors,¹⁶
including the cognitive demands of a task.²³ Indeed, McLaren et al.²⁴ recently
demonstrated that cognitive RPE explained a significant proportion of variance
in session RPE reported during rugby conditioning sessions. However, others
have reported no difference in RPE when performing a mentally demanding
task during exercise;²⁵ additional explanations for the observed increase in RPE
are therefore needed.

284

304

285 The greater vigilance required to correctly respond to the commands in the STOCH trial potentially resulted in participants adopting a greater associative 286 287 attentional focus (i.e. participants' attention was directed toward pertinent 288 information associated with completing the RLMSP-i, such as sprinting to the correct cone).¹⁰ If true, this could explain the higher RPE and increased sprint 289 performance in the STOCH trial. Task association can increase RPE relative to 290 task dissociation,²⁶ due to a greater internal focal awareness of physiological 291 292 sensations. Furthermore, task association, particularly when it is external 293 (where attention is focussed on completing the outcome of the task rather than 294 the bodily movements required and associated physiological responses), can enhance performance across a variety of exercise tasks, such as maximal force 295 296 production, vertical jumping, sprinting and endurance exercise.¹⁵ An 297 alternative explanation for our observations of altered performance is that the 298 CON trial induced more boredom, which has can negatively affect exercise 299 intensity ²⁷. However, a limitation of our research is that we did not assess 300 attentional focus or boredom, and therefore such a mechanism for our 301 observations is speculative. Further research should explore the influence of 302 attentional focus on simulated team sport performance with differing mental 303 demands.

305 Afferent feedback from multiple physiological systems is thought to influence RPE,¹⁶ and both heart rate and B[La] are related to athletes' RPE during small-306 sided games.²⁸ In the present study, %HRmax was not different between trials, 307 308 and is therefore unlikely to have resulted in a higher RPE. The lower B[La] in 309 the STOCH trial might be expected to be associated with a lower RPE. 310 However, the reliability of B[La] measured during the RLMSP-i is poorer than other measures (CV% = 13.4 - 19.7%; interchange bout 1 and 2, respectively). 311 It is also well established that work performed immediately before sampling 312 influences blood lactate concentrations.²⁹ After the final maximal intensity 313 effort (20 m maximal sprint and 8 m sprint to contact), there was 1.11 min and 314 315 0.26 min until the end of the protocol for CON and STOCH, respectively. 316 Given that participants seemingly have an increased external load during 317 STOCH (i.e. sprinting faster and covering more distance), the higher blood 318 lactate concentration during CON is likely to reflect the movement activity 319 before sampling rather than an overall increase in exercise intensity (which 320 might increase in RPE). 321

For the first time, this study assessed changes in MVC and VA% after a simulated rugby league match. The proportional decrease in MVC and VA% response was similar after the STOCH (12 and 7%, respectively) and CON (14 and 9%, respectively) trials. The MVC response is comparable to the mean values reported for rugby league players immediately (8 ± 11%) and two hours

after competitive match play ($12 \pm 13\%$).³⁰ However, Duffield et al.³⁰ reported 327 no difference in VA% when comparing baseline $(90.1 \pm 6.7\%)$ to immediately 328 329 (-0.4%) and two hours (-0.8%) after match play. These disparities in VA% 330 reported after actual and simulated rugby league match play might be due to procedural differences, such as stimulation site, stimulation frequency, the 331 exercise intensity of the RLMSP-i and participant training status.³¹ It is also 332 possible that the greater amount of high intensity running in the current 333 protocol (\sim 1230 m) compared to that reported by Duffield et al.³⁰ (\sim 877 m), 334 335 induced a greater degree of central fatigue. Nonetheless, the observed 336 decrement in VA% in STOCH (-6.5%) and CON (-9.1%) trials of the RLMSP-337 i when compared to baseline $(92.9 \pm 4.5\%)$ and $91.3 \pm 8.1\%$, respectively), 338 suggest reductions in force generating capacity of the knee extensors after 339 movements replicating rugby league match play are due to both central and peripheral mechanisms.¹⁶ 340 341

The similar neuromuscular response to both conditions is consistent with research reporting no difference in both MVC and VA% after periods of mental exertion.³² Unlike the negative effects of mental fatigue on endurance performance,³³ mental fatigue seemingly does not impair maximal force production over a short duration.³² This might explain why greater maximal sprints occurred in the stochastic protocol, despite the small potential increase in mental demand.

350 The present study has several limitations that should be acknowledged. As we 351 previously stated, the proposed mechanism of the STOCH trial being affected 352 by task association is speculative and would have benefited from a direct attempt to assess attentional focus. However, these methods are associated with 353 numerous threats to validity.³⁴ Secondly, whilst we endeavoured to ensure that 354 the number, type and relative spacing of demanding activities – such as 355 sprinting - were as well-matched between protocols as feasible, it cannot be 356 357 discounted that the activity performed immediately before and after demanding activities influenced their outcome. Whilst this, in itself, is a notable outcome 358 359 of this research, future studies might wish to explore the extent to which this, 360 rather than altered mental demands for example, affects simulated team sport 361 performance. Thirdly, we acknowledge that the new STOCH protocol, which 362 does not have short (~115 s) repeated cycles of activity, cannot be used to 363 compare performance between distinct small time periods (for example, 364 changes across 2 min periods), given that no two short periods will be the same. 365 However, given that we have matched the number and frequency of commands for each ~5.45 min, we feel that changes over approximately 5 min can be 366 explored with the STOCH protocol. Finally, we acknowledge that some of 367 368 our observed effects have confidence intervals that contain zero or the interval demarcating a 'trivial' effect (i.e. ES = -0.2 to 0.2). As such, we 369 370 encourage researchers to replicate and/or extend our investigation to 371 clarify if more stochastic simulation protocols do indeed change perceived 372 mental demands and elements of running performance.

Practical Implications

373

Those designing team sport simulation protocols should note that
 physiological, perceptual and performance responses can be influenced by the

- order of events that are performed. Such differences might have importantimplications for the validity of team sports protocols.
- More repetitive movement patterns, which require less vigilance, might reduce
 repeated sprint performance in team sports protocols. We propose that less
 predictable movements be used when seeking to maximise external work in
 players.
- These findings also have implications for those seeking to replicate the movement and mental demands of match play in training situations and promote the use of practices that employ stochastic rather than repetitive movements, e.g. small-sided games.
- 387

388 Conclusions

389 Manipulating the order of events to be more stochastic during a simulation of 390 rugby league match-play potentially increases the mental demand of this 391 activity, which appeared to be associated with increased self-paced sprint 392 performance, impaired decision making capacity and increased perceived 393 exertion. Accordingly, when simulating match play, the cognitive demand and 394 vigilance requirement associated with the task should be considered. 395 Investigations into the mental demands of competitive rugby league match play are needed, such that valid training and research replications of match demands 396 397 can be made. 398

Table 1. Speed, low intensity activity (<14 km h⁻¹), high intensity running

| 511 | (≥14 km [.] h ⁻¹ |), mean sprint | speed, player | load and time | at high metabolic | power for control |
|-----|--------------------------------------|----------------|---------------|---------------|-------------------|-------------------|
|-----|--------------------------------------|----------------|---------------|---------------|-------------------|-------------------|

| 512 | and random trials during the whole simulation | . Mean \pm SD, Effect Size (\pm 95% CI) | |
|-----|---|--|--|
| | | E 1 / 1 | |

| | Trial | | 513 ES (050/ ED) |
|---|----------------|---------------|----------------------------|
| | CON | STOCH | - ES (95% §14 |
| Speed (m ^{-min⁻¹}) | 104.0 ± 5.1 | 105.5 ± 4.0 | $0.26 (0.44)_{516}$ |
| Low (m ^{-min⁻¹}) | 77.0 ± 3.9 | 77.8 ± 3.8 | $0.19\ (0.80)^{517}_{518}$ |
| High (m ^{-min⁻¹}) | 26.7 ± 4.9 | 27.7 ± 4.3 | 0.19 (0.68519 |
| Sprint to Contact (km ⁻¹) | 13.2 ± 1.4 | 13.5 ± 1.1 | $0.17 (0.48)_{521}^{520}$ |
| Sprint Speed (km ⁻ h ⁻¹) | 21.6 ± 1.6 | 22.5 ± 1.4 | $0.50 (0.55)_{522}^{521}$ |
| PlayerLoad TM (AU) | 459 ± 52 | 450 ± 47 | 0.17 (0.53)523 |
| Metabolic Power >20 W kg ⁻¹ (s) | 246 ± 40.2 | 252 ± 48 | $0.11(0.63)_{525}^{524}$ |
| | | | 526 |

Low = low intensity activity, <14 km h⁻¹; High = distance covered high speed running, \geq

km h⁻¹ per minute; Sprint to Contact = maximum speed achieved during the 8 m sprint to

contact; Sprint Speed = an average of the maximum speed during each 20 m sprint.

Table 2. Physiological, perceptual and neuromuscular responses to the RLMSP-i. Mean \pm SD, effect size (\pm 95% CI).

| | Trial | | ES | |
|---------------------------|----------------|----------------|---------------|--|
| | CON | STOCH | (95% CI) | |
| %HR _{max} | 83.1 ± 7.2 | 81.9 ± 3.9 | 0.15 (0.38) | |
| B[La] (mmol ⁻¹ |) | | | |
| - Pre | 2.5 ± 1.1 | 2.6 ± 0.7 | 0.10 (0.64) | |
| - Mid | 6.0 ± 2.5 | 4.9 ± 1.9 | 0.40 (0.39) | |
| - Post | 5.9 ± 2.7 | 5.1 ± 5.9 | 0.28 (0.39) | |
| RPE | 13.0 ± 1.4 | 14.3 ± 1.0 | 0.87 (0.67) | |
| <i>s</i> RPE | 5.5 ± 1.8 | 6.5 ± 1.3 | 0.52 (0.60) | |
| Peak torque (N· | m) | | | |
| - Pre | 331.1 ± 79.9 | 318.6 ± 76.3 | 0.56 (0.30) & | |
| - Post | 282.7 ± 80.7 | 279.0 ± 66.8 | 0.48 (0.25)* | |
| VA (%) | | | | |
| - Pre | 91.3 ± 8.1 | 92.9 ± 4.5 | 0.95 (0.68) & | |
| - Post | 83.0 ± 8.0 | 86.9 ± 7.4 | 1.23 (1.04)* | |

%HRmax = percentage of heart rate maximum; RPE = rating of perceived exertion; sRPE = session rating of perceived exertion. VA = voluntary activation. * Refers to the pre-post change for CON and STOCH, respectively.

Table 3. Reaction time and accuracy during the Stroop test for control and random trials,

Mean \pm SD, Effect Size (\pm 95% CI).

| | Trial | ES (050/ CI) | |
|--------------|-----------------|------------------|---------------|
| _ | CON | STOCH | - ES (95% CI) |
| ST - Time (s |) | | |
| Pre | 75.6 ± 5.3 | 76.9 ± 5.8 | 0.21 (0.71) |
| Mid | 73.6 ± 7.3 | 73.2 ± 6.5 | 0.06 (0.49) |
| Post | 72.2 ± 4.3 | 75.0 ± 4.3 | 0.59 (0.62) |
| Total | 221.5 ± 15.1 | 225.1 ± 14.5 | 0.22 (0.49) |
| ST - Attempt | ts (<i>n</i>) | | |
| Pre | 9.5 ± 1.6 | 10.4 ± 3.2 | 0.51 (0.77) |
| Mid | 9.7 ± 2.0 | 9.3 ± 1.3 | 0.21 (0.56) |
| Post | 9.3 ± 1.4 | 10.3 ± 2.5 | 0.65 (0.83) |
| Total | 28.5 ± 4.4 | 29.9 ± 6.5 | 0.30 (0.54) |

543 ST-time = Stroop test reaction time; ST-attempts = Stroop test number of attempts.
