31 Abstract

32 To date, no research has explored the effects of low energy availability (EA) on cognitive performance using dietary and exercise regimens relevant to athletes. Twenty female participants (10 eumenorrheic, 10 oral 33 34 contraceptive [OC] users) completed three, 3-day conditions: 1) controlled-balanced EA without exercise (BAL; 45 kcal·kg·LBM⁻¹·day⁻¹), 2) diet-induced low EA without exercise (DIET; 15 kcal·kg·LBM⁻¹·day⁻¹) and 3) 35 36 exercise-induced low EA (EX; 15 kcal·kg·LBM⁻¹·day⁻¹, including 30 kcal·kg·LBM⁻¹·day⁻¹ treadmill running at 37 70% VO_{2max}). A cognitive test battery was completed before and after each 3-day condition. Mental rotation test 38 accuracy improved in the BAL condition, but there was a decline in accuracy in the EX condition (BAL, +2.5%; 39 EX, -1.4%; P = 0.042, d = 0.85). DIET (+1.3%) was not different to BAL or EX (P > 0.05). All other measures 40 of cognitive performance were not affected by condition (P > 0.05) and OC use did not affect cognitive responses 41 (P > 0.05). Accuracy in the mental rotation test was impaired when low EA was induced through increased 42 exercise energy expenditure. All other aspects of cognition were unaffected by three days of low EA through diet 43 or exercise. OC use did not mediate the effect of low EA on cognition. 44 Keywords: Cognition, energy availability, diet, exercise, females, oral contraceptives 45 46 Novelty

• Cognitive function was not affected by 3 days diet-induced low energy availability (EA).

• Only spatial awareness was impaired during 3 days exercise-induced low EA.

- 49 Reproductive hormones affected spatial awareness independent of EA.

58 Introduction

59 Energy availability is the amount of dietary energy available to maintain physiological function after exercise 60 training (Loucks et al. 2011). Athletes, military recruits and dieters often restrict energy intake, expend large 61 amounts of energy in exercise, or undergo a combination of these practices, which can result in low energy 62 availability (Loucks et al. 2011; De Souza et al. 2014). Low energy availability (<30 kcal·kgLBM⁻¹) is common 63 in female athletes and recreationally active individuals and is associated with menstrual dysfunction and impaired 64 bone health (Nattiv et al. 2007; De Souza et al. 2014; Slater et al. 2016) and it has been suggested that many other 65 components of health and performance may also be affected (Mountjoy et al. 2014, 2018). The Relative Energy 66 Deficiency in Sport (RED-S) model has proposed that low energy availability may negatively affect several 67 factors relating to exercise performance, including aspects of cognition (Mountjoy et al. 2014), although there is 68 currently little evidence available to support this (De Souza et al. 2014b; Williams et al. 2019) and the effects of 69 low energy availability on cognition remain unclear.

70

71 To date, only two studies have examined the effects of short term (2-3 days) low energy availability on cognitive 72 performance. In the first study, two days of near total calorie deprivation (~183 kcal·day⁻¹ energy intake), was 73 compared to energy-balanced conditions, consisting of either carbohydrate or carbohydrate and fat diets (~2820 74 kcal·day⁻¹ energy intake), with all conditions including two hours of low intensity exercise (40-45% heart rate 75 reserve) per day (Lieberman et al. 2008). Consuming the calorie-restricted diet did not impact participants' self-76 reported mood and had no effect on vigilance, response time, memory, and reasoning skills. In the second study, 77 participants completed approximately four hours of exercise per day (40-65% VO_{2peak}) and consumed either an 78 energy-balanced (3935 \pm 769 kcal·day⁻¹ energy intake), or calorie-restricted (266 \pm 61 kcal·day⁻¹ energy intake) 79 diet (Lieberman et al. 2017). Mood was significantly affected, with reduced vigour and increased tension, fatigue 80 and total mood disturbance occurring in the calorie-restricted condition, which was associated with a significant 81 reduction in interstitial glucose concentrations. Performance on the majority of cognitive tests was unaffected, 82 although aspects of grammatical reasoning and choice reaction time were improved in the calorie-restricted 83 condition compared to the energy-replete condition, potentially resulting from an evolutionary response of 84 heightened cognitive function in the presence of food scarcity (Bronwen et al. 2007).

86 In these studies (Lieberman et al. 2008, 2017), changes in cognitive performance were only apparent when a
87 greater exercise duration and intensity was used (Lieberman et al. 2017), which resulted in a greater deviation

88 from energy balance (-3681 kcal· d^{-1} compared to -2138 kcal· d^{-1} in the earlier study), despite similar dietary energy 89 intakes. The severity of the dietary restriction and exercise energy expenditure used in these studies would have 90 resulted in a negative energy availability, which is only representative of extreme situations such as military 91 training and does not represent the practices of athletes or exercising populations. Energy availability values in 92 athletes are often between ~8-35 kcal·kgLBM⁻¹day⁻¹ (Loucks et al. 2011; Van Heest et al. 2014; Vogt et al. 2005), 93 which are achieved through more moderate levels of dietary energy restriction, or a failure to increase energy 94 intake to compensate for exercise training (De Souza et al. 2014). Therefore, further research using more 95 ecologically valid levels of energy availability and methods of achieving this (*i.e.*, dietary restriction and/or 96 exercise) is required. Furthermore, these studies (Lieberman et al. 2008; Lieberman et al. 2017) have not used a 97 non-exercise control, or dietary restriction only group, making it difficult to differentiate the effects of low energy 98 availability from the effects of exercise (Chang et al. 2012; Tomporowski 2003).

99

100 Lieberman et al. (2017) identified an effect of sex on the response to calorie-restriction, whereby females (n = 6)101 performed better in tests of working memory, grammatical reasoning and vigilance in the calorie-restricted 102 condition compared to when energy replete, while this effect was not apparent in males (n = 17). This sexually 103 dimorphic response may be mediated by differences in reproductive hormone concentrations; therefore, the 104 reproductive hormone milieu should be considered in future research. Research in exercising females should 105 assess both hormonal contraceptive users and non-users in order to provide a representative sample (Martin et al. 106 2018), whilst also reflecting the different endogenous and exogenous reproductive hormone concentration 107 between these groups. Combined oral contraceptive (OC) users consume synthetic oestrogens and progestins and 108 have down-regulated endogenous reproductive hormone concentrations (Elliott-Sale et al. 2013), whilst oestrogen 109 and progesterone concentrations are greater in eumenorrheic women and fluctuate in a cyclical manner across the 110 menstrual cycle (Stricker et al. 2006). A further reason why female participants should be explored is that 111 reproductive function is sacrificed during periods of low energy availability resulting in a down-regulation of 112 reproductive hormones (Loucks et al. 1998). This alteration to the reproductive hormone profile could exacerbate 113 or ameliorate the effects of low energy availability on cognition as performance in some domains of cognitive 114 function (e.g., verbal memory) are positively correlated to oestrogen (Rosenberg and Park 2002), while 115 performance in other domains (e.g., spatial awareness) are negatively associated with oestrogen (Hausmann et al. 116 2000)

Given the lack of previous research that has explored the effects of short-term low energy availability in exercising women, the aims of this study were to: 1. Compare the cognitive effects of short term balanced energy availability (45 kcal·kgLBM·day⁻¹) to a level of low energy availability representative of athletes (15 kcal·kgLBM·day⁻¹) achieved through dietary restriction or exercise and, 2. Examine whether the cognitive responses were different in eumenorrheic women and oral contraceptive users.

123

124 Materials and methods

125 Participants

126 Twenty recreationally active participants (10 eumenorrheic, 10 OC users), who exercised for at least 4 h week⁻¹ 127 as measured by the International Physical Activity Questionnaire (IPAQ; Craig et al. 2003), volunteered to take 128 part in the study (participant characteristics shown in Table 1). Eumenorrheic participants had a regular menstrual 129 cycle in the 6 months prior to taking part, with a cycle length of between 24-35 days and used no form of hormonal 130 contraception. Oral contraceptive participants used combined, monophasic low-dose formulations (Microgynon® 131 n=5; Yasmin \mathbb{B} n = 2; Rigevidon \mathbb{B} n = 1; Gederal \mathbb{B} n = 1; Milinette \mathbb{B} n = 1) throughout the duration of the study 132 and for at least 6 months prior to taking part. All participants were not at risk of an eating disorder, as characterised 133 by their score (≤ 2) on the SCOFF eating disorder questionnaire (Morgan et al. 1999). Exclusion criteria for 134 participation were: aged < 18 or > 40 years, current smokers, musculoskeletal injury, use of medication that may 135 affect outcome measures, bone fracture in previous 12 months, history of metabolic, heart, liver or kidney disease, 136 diabetes, thyroid disorders, breastfeeding women, women trying to become pregnant or women with amenorrhea, 137 short, long, or irregular cycles. Participants provided their informed consent and the study was approved by the 138 Nottingham Trent University Research (Human) Ethics Committee and the East Midlands NHS Research Ethics 139 Committee (14/EM/1156), in accordance with the Declaration of Helsinki.

140

141 Experimental Design

The study design has previously been described elsewhere (Papageorgiou et al. 2018) as the current study forms part of a larger project. Prior to taking part in the experimental conditions, a preliminary assessment was undertaken to determine body composition and maximal oxygen uptake ($\dot{V}O_{2max}$) and to familiarise participants with the cognitive function test battery. All participants then completed three, 3-day experimental conditions in a crossover design; 1) controlled energy balance (BAL), 2) diet-induced low energy availability (DIET) and 3) exercise-induced low energy availability (EX) (Figure 1). Participants were randomly allocated to complete the 148 experimental conditions in a counter-balanced order, using a Latin-square design, but due to participant 149 availability, 6 out of 20 participants were unable to complete the sessions in the specified order. Dietary energy 150 intake (DEI), exercise energy expenditure (EEE) and the resultant energy availability for each condition are 151 displayed in Figure 1. For each condition, a blood sample and cognitive function assessment were conducted at 152 baseline (PRE) and following (POST) the 3-day condition. PRE-testing was conducted in the morning either the 153 day before, or the day of, the start of the experimental condition dependent upon participant availability, whilst 154 POST-testing was always completed in the morning following completion of the 3-day experimental condition. 155 Within-participant testing was conducted at the same time for each session (07:15-8:15) to account for diurnal 156 variation (Sedliak et al. 2008). Participants were asked to consume 500 ml of water upon awakening and refrain 157 from exercise in the 24 h before PRE-testing. Experimental conditions were completed in the early follicular phase 158 of the menstrual cycle for eumenorrheic participants with POST-testing occurring within 7 days of the onset of 159 menstrual bleeding to limit changes in reproductive hormone concentrations (Stricker et al., 2006). Testing was 160 completed during the first week of pill consumption for OC users to ensure consistency between participants. Oral 161 contraceptive users were asked to consume their pill 1 h prior to arrival to the laboratory and asked to consume it 162 at this time for the duration of the study.

163

164 Experimental Protocol

165 Preliminary assessment

166 Lean body mass was (LBM) measured using a whole-body duel-energy x-ray absorptiometry (DXA) scan (Lunar 167 iDXA, GE Healthcare, Illinois, USA) in order to prescribe individualised diet and exercise regimens. All scans 168 were performed by a qualified DXA practitioner and calibration was conducted prior to all scans with a phantom 169 as per manufacturer's guidelines. Participants were scanned in minimal clothing with all metal objects removed 170 and were aligned centrally on the scanning bed. Participants were asked to arrive at the laboratory in a rested state, 171 at least 3 h post-prandial and euhydrated due to the known effects of exercise, food intake and hydration on DXA 172 scan results (Nana et al. 2015). Urine osmolality was checked prior to scanning and had to be $< 800 \text{ mOsm} \cdot \text{kg}^{-1}$, 173 otherwise participants consumed water until the appropriate osmolality was achieved.

174

 VO_{2max} was determined using a two-stage method consisting of a speed lactate test to determine running speed at lactate threshold, and a ramp test to exhaustion (Jones 1998). Lactate threshold was determined using an incremental treadmill (h/p cosmos, Nuβdorf, Germany) test with 3 min stages beginning at 7-9 km·h⁻¹ depending 178 upon participant training history and familiarity with treadmill running. Between each stage there was a 1 min rest 179 period in which a capillary blood sample was taken to determine blood lactate concentration (YSI 2300 Stat Plus, Ohio, USA). Treadmill speed was increased by 1 km·h⁻¹ per stage until blood lactate concentration increased by 180 181 1 mmol·L⁻¹ during one stage or was > 4 mmol·L⁻¹. After a 10 min rest, participants began an exhaustive treadmill 182 exercise test at the speed corresponding to the stage immediately before a significant increase in blood lactate 183 concentration was observed. Initial treadmill incline was 0 % and was increased 1 % every minute until volitional 184 exhaustion. Breath-by-breath analysis of expired air was conducted (ZAN600 CPET, nspire, Oberthulba, 185 Germany) to determine $\dot{V}O_{2max}$.

186

187 PRE and POST condition testing

188 Upon arrival to the laboratory, height (Seca 217, Birmingham UK) and body mass (Seca 875, Birmingham, UK) 189 were measured and 30 ml of blood was drawn using venepuncture for analysis of 17-β-oestradiol concentrations 190 and other hormones and metabolic markers which are published elsewhere (Papageorgiou et al. 2018). Following 191 this, participants completed the Brunel Mood Scale (BRUMS; Terry et al. 1999) to assess mood state (Tension, 192 Depression, Anger, Fatigue, Confusion, Vigour) and the Pittsburgh Sleep Quality Index (PSQI; Buysse et al. 1989) 193 to measure self-reported sleep quality. Mood and sleep quality were measured are they known to impact cognitive 194 function (Benitez & Gunstad, 2012; Chepenik et al., 2007) and therefore can provide context to results A cognitive 195 test battery was then completed in a quiet area, with participants seated at a desk facing a blank wall to minimise 196 distractions. During verbal tests, the experimenter was seated directly behind the participant approximately 1 m 197 away and participants were instructed to face away from the experimenter throughout the tests. For computer-198 based tasks (mental rotation test, Stroop test, rapid visual information processing [RVIP], visual search), a laptop 199 (Elitebook, hp, California, USA) was loaded with cognitive software (Sensitive Cognitive Assessment Inventory, 200 Loughborough, UK), lights were dimmed for optimal screen visibility and sound-cancelling headphones were 201 worn to prevent distractions. Written instructions appeared on the screen before each cognitive task, which were 202 reinforced with verbal instructions, and participants' understanding of the test was confirmed by checking that 203 correct responses were provided during pre-test practice stimuli. For the computer-based tasks, participants were 204 asked to get as many correct as possible, but to respond as quickly as they could in order to assess both accuracy 205 and response time. All cognitive tests were performed during each PRE or POST trial and the order the tests were 206 completed was standardised as presented below. Cognitive tests were selected to incorporate domains of cognitive 207 function that have previously been related to reproductive hormone concentrations (verbal memory and spatial

awareness; Poromaa & Gingnell, 2014) and energy restriction (memory, psychomotor function, attention and
executive function; (Green et al., 1994, 2005; Kemps et al., 2005).

210

211 *Rey auditory verbal learning test (RAVLT)*

212 The RAVLT is an oral memory test that measures immediate memory span, new learning and susceptibility to 213 interference (Rey 1941). A list of 15 words (List A) was read aloud (with a 1 s interval between words), for five 214 consecutive trials (Trials 1 to 5), each followed by a free-recall test in which participants were asked to recall as 215 many words as possible from the list in any order. The order of the presentation of the words remained fixed 216 across trials. On completion of Trial 5, an interference list of 15 words (List B) was presented, followed by a free 217 recall of that list. Immediately after this, participants were asked to recall List A without further presentation of 218 these words (Trial 6). After a delay period in which the remainder of the cognitive tests were conducted (~20 min) 219 the participant was then required to recall words from List A without hearing them again (Trial 7). Time limits 220 were not imposed and participants were asked to inform the experimenter when they could not remember any 221 more words. Acquisition (sum of words recalled across Trials 1-7 and List B), learning rate (difference between 222 Trial 1 and Trial 5), proactive interference (difference between Trial 1 and List B), retroactive interference 223 (difference between Trial 5 and Trial 6) and forgetting (difference between Trial 7 and Trial 5) were calculated 224 (Strauss et al. 2006). No feedback was given regarding the number of correct responses until completion of the 225 study. Six alternate words lists were used in a counterbalanced order for the RAVLT during the main experimental 226 trials, which were matched for word frequency, length and serial position and have good levels of equivalency 227 (Lezak 1983; Geffen et al. 1994; Majdan et al. 1996; Crawford et al. 1989; Shapiro and Harrison 1990).

228

229 Mental rotation test

230 An adapted version of the mental rotation test (Vandenberg and Kuse 1978) was used to measure spatial awareness. 231 Participants were required to select, using the left and right arrow keys, which of the two three-dimensional shapes 232 at the bottom of the screen could be rotated to match the shape in the centre of the screen. Each trial consisted of 233 6 practice stimuli in which feedback was provided for correct and incorrect responses, followed immediately by 234 a main trial with 50 stimuli, equally distributed between 0, 20, 40, 60 and 80 degrees of rotation, relative to the 235 central shape, in a randomised order. Task difficulty was increased with greater degrees of rotation (Cooperau and 236 Shepard 1973) so the effects of increasing task complexity could be assessed. The variables of interest were 237 accuracy and the response time of correct responses. For response time analysis, a minimum response time of 200

ms and a maximum response time of 20000 ms was set to remove any anticipatory or unreasonably slow response times. Tests of mental rotation have a good internal consistency (Kuder-Richardson 20 = 0.88 and Cronbachs α = 0.91; Vandenberg and Kuse 1978; Cassie et al. 2009) and test-retest reliability (0.83; Vandenberg and Kuse 1978).

241

242 Visual Search test

243 The Visual Search test is a computer-based test assessing response time and simple visuo-motor speed consisting 244 of two difficulty levels. In the simple level, 20 stimuli were presented and participants were required to press the 245 space bar as quickly as possible when a green triangle was presented on a black background. In the complex level, 246 green dots were randomly distributed across the screen, which were redrawn every 250 ms to induce the effects 247 of a flickering background and act as a distractor. The outline of a triangle was progressively drawn on the 248 background in green dots, with the density of the dots increasing over time. The participants were required to 249 press the space bar as soon as they identified the triangle for a total of 50 stimuli. In both test levels, the location 250 of the triangle stimulus was random and the variables of interest were accuracy and the response time of correct 251 responses. A minimum response time of 300 ms and a maximum response time of 1500 ms (simple level) and 252 10000 ms (complex level) was set to remove any anticipatory or unreasonably slow response times. The test has 253 previously been shown to be reliable for both difficulty levels (r > 0.80; Bandelow et al. 2011).

254

255 *Stroop-Colour test*

256 The Stroop-Colour test (Stroop 1935), is a computer-based test of inhibitory control that measures the ability to 257 suppress automated responses (Strauss et al. 2006). In the simple level, one of three words (RED, BLUE or 258 GREEN) was written in white font in the centre of the screen, with a matching word and non-matching word 259 either side, also in white font. Using the arrow keys, participants selected the word which matched the middle 260 word as quickly as possible for a total of 20 stimuli. In the complex level, participants were provided with a word 261 in the centre of the screen (e.g. GREEN), written in a different colour font (e.g. blue font). This time, the 262 participant was asked to choose the word corresponding to the font colour of the central word, rather than the 263 written text, as quickly as possible for a total of 50 stimuli. The variables of interest were response time of correct 264 responses and accuracy. A minimum response time of 250 ms and a maximum response time of 2500 ms (simple 265 level) and 4000 ms (complex level) was set to remove any anticipatory or unreasonably slow response times. The 266 test has previously been shown to be reliable for both the simple and complex (r > 0.85) levels (Bandelow et al. 267 2011).

268

269 Rapid Visual Information Processing task

270 The Rapid Visual Information Processing (RVIP) task is a computer-based measure of sustained attention, 271 working memory and selective attention, adapted from the continuous performance task (Wesnes and Warburton 272 1984). Digits between 2 and 9 appeared in a pseudo-random order in the centre of the screen at a rate of 100 273 numbers min⁻¹ for 5 min. Participants were instructed to press the space bar when either 3 consecutive even, or 3 274 consecutive odd numbers appeared. Correct responses were accepted for 1500 ms after the final digit of each 275 sequence. There were a total of 40 correct sequences to identify. The proportion of correct responses out of all 276 responses (true positive rate), the proportion of missed targets (miss rate) and the response time of correct 277 responses was recorded. A minimum response time of 200 ms and a maximum response time of 1500 ms was set 278 to remove any anticipatory or unreasonably slow response times. Prior to each test, participants were provided 279 with a practice attempt to identify a total of 4 sequences, where feedback was provided to show correct or missed 280 responses. The test has previously been shown to be reliable for both the true positive rate (r = 0.85) and miss rate 281 (r = 0.79), however response time had moderate reliability (r = 0.53); Bandelow et al. 2011).

282

283 *Diet and Exercise protocol*

284 During the 3-day experimental periods, participants were provided with diets according to the experimental 285 condition (Figure 1). Diets were individually weighed and separated into containers. The diets consisted of cereals, 286 milk, vegetable soups, pitta bread, salad and chicken/fish and were palatable and easy for participants to prepare 287 to enhance compliance. The macronutrient composition of the diets was 50% of energy intake from carbohydrate, 288 30% from fat and 20% from protein; diets were designed by a registered dietician. During each 3-day experimental 289 period, participants were asked to consume all the food provided, have their meals at similar times both within 290 and between conditions and not to consume any other food or caloric beverages. During the DIET condition, a 291 multivitamin and mineral supplement (Boots A-Z, Nottingham, UK) was provided for daily consumption to 292 provide adequate micronutrient intake and isolate the effects of low energy availability/macronutrient restriction. 293 Participants were asked not to participate in any exercise during the experimental conditions (e.g. cycling to work, 294 running, gym, training), unless as part of the experimental protocol, which was confirmed verbally with 295 participants.

For the EX condition, participants performed treadmill running equivalent to a total energy expenditure of 30 kcal·kgLBM·day⁻¹ (Figure 1), which was separated into two exercise sessions; one in the morning and one in the afternoon. This consisted of repeated 15 min running bouts at 70% $\dot{V}O_{max}$, with 5 min rest between bouts, until energy expenditure reached the required amount as determined through breath-by-breath analysis (ZAN, nSpire, HDpft 3000). Breath-by-breath analysis was used for the initial morning exercise session and the values were used to calculate running speed and duration for subsequent exercise sessions.

303

304 Biochemical analysis

Blood was drawn from an antecubital forearm vein and separated into serum tubes, which were left to clot at room temperature for 30 minutes. Serum was centrifuged at 3000 rev·min⁻¹ at 4°C for 10 minutes, transferred into Eppendorf tubes and frozen at -80°C. 17- β -oestradiol was analysed using an electro-chemiluminescence immunoassay (ECLIA; Roche, Basel, Switzerland) with an inter-assay coefficient of variation (CV) of < 4.3% between 214.3-2156.7 pmol·L⁻¹ and a detection limit of 18.4 pmol·L⁻¹.

310

311 Statistical Analysis

312 Eumenorrheic and OC participants' demographic information was compared using an independent samples t-test. 313 A one-way repeated-measures ANOVA was used to assess for differences between conditions at baseline. Change 314 from pre- to post-condition for RAVLT, RVIP, BRUMS and PSQI data were calculated and analysed using a two-315 way (group x condition) mixed-model ANOVAs using Statistica (Dell, Texas, USA). Three-way (group x 316 condition x level) mixed-model ANOVAs were used to assess mental rotation test, Stroop test and visual search 317 test performance as these tests are comprised of different difficulty levels, reflecting different aspects of cognition. 318 17-β-oestradiol concentration was analysed using a three-way (group x condition x time) mixed-model ANOVA. 319 Data were checked for normality using Shapiro-Wilk tests and significant effects were explored with Bonferroni-320 adjusted t-tests, with effect sizes calculated using Cohens' D (0.2 = small, 0.5 = medium, 0.8 = large; Cohen and 321 Jacob 1992). All data are presented as mean \pm 1SD and statistical significance was set at P \leq 0.05.

322

323 **Results**

324 There were no differences in any demographic variable between eumenorrheic women and OC users (all P <

325 0.05).

327 *Cognitive function*

328 The mean data for all cognitive function tests can be found in Table 2. There were no differences between 329 conditions at baseline for any of the cognitive function measures (all P > 0.05), therefore data were analysed and 330 are presented as change from pre- to post-condition.

331 The changes from pre- to post-condition for the RAVLT, visual search test, Stroop test and RVIP task were not 332 affected by condition, group or test level (visual search test, Stroop test), and there were no significant interactions 333 between these factors (all P > 0.05). The change from pre-to post-condition was different between conditions for 334 accuracy in the mental rotation test (main effect of condition, P = 0.045; Table 2). As change data were analysed, 335 this is indicative of a divergence in performance over time, between conditions. Post-hoc tests showed that whilst 336 accuracy improved in the BAL condition, there was a decline in accuracy in the EX condition (BAL, +2.5%; EX, 337 -1.4%; P = 0.042, D = 0.85). DIET (+1.3%) was not different to BAL or EX (P > 0.05; Figure 2). There was a 338 significant difference between groups for response times in the mental rotation test (main effect of group, P =339 0.017), whereby response time was improved to a greater extent from pre-to post-condition in OC users (-13.7%) 340 compared to eumenorrheic participants (-4.0%, P = 0.017; D = 0.67). Response time was improved to a greater 341 extent from pre-to post-condition at 80° compared to 0° rotation (P = 0.005, D = 0.29). Accuracy was improved 342 to a greater extent from pre-to post-condition at 80° compared to 0° and 20° rotation (both P < 0.005) and at 40° 343 compared to 20° (P = 0.031).

344

345 Brunel Mood Scale

346 There was no effect of group on any component of the BRUMS score (main effect of group, all P > 0.05) and 347 group did not influence the response to each condition (group x condition interaction, all P > 0.05). The condition 348 influenced the change from pre- to post-condition for Anger, Confusion and Fatigue (main effect of condition, all 349 P < 0.05). Post-hoc tests showed that whilst Anger increased in the DIET condition, it was reduced in the EX 350 condition (BAL, +0.85; EX, -0.6; P = 0.010, D = 0.854; Figure 3) and was not different in BAL (-0.1) compared 351 to DIET or EX conditions (P > 0.05). Confusion was reduced in the BAL condition and increased in the DIET 352 condition (BAL, -0.75; DIET, +0.45; P = 0.005, D = 0.461), with EX (-0.3) not different to BAL or DIET 353 conditions (P > 0.05). Fatigue was reduced in the BAL condition and increased in the EX condition (BAL, -0.9; 354 EX, +1.45; P = 0.027, D = 0.802), while DIET (+0.65) was not different to BAL or EX (P > 0.05)

- There was no effect of condition on sleep quality (main effect of condition, P = 0.702) and group did not influence the response between conditions (group x condition interaction effect, P = 0.572). There was a significant difference between eumenorrheic (-0.133) and OC (+1.167) participants for PSQI score change from pre- to postcondition (main effect of group, P = 0.017, D = 0.59; Table 3).
- 361

362 *17-β-oestradiol concentration*

- Mean plasma 17-β-oestradiol concentration was significantly higher in eumenorrheic (143.0 ± 62.6 pmol·L⁻¹) than OC (51.2 ± 53.5 pmol·L⁻¹) participants (main effect group; P < 0.001, D = 1.58). There was a significant time x group interaction (P < 0.001); 17-β-oestradiol concentrations were reduced from pre (73.8 ± 68.1 pmol·L⁻¹) to post (28.5 ± 11.2 pmol·L⁻¹; P = 0.03, D = 1.141) condition in OC participants and were not different from pre (125.4 ± 59.9 pmol·L⁻¹) to post (160.7 ± 61.1 pmol·L⁻¹) condition in eumenorrheic participants (P = 0.129, D = 0.58; Table 4). There was no effect of condition on 17-β-oestradiol concentrations and condition did not interact with group or time (P > 0.05).
- 370

371 **Discussion**

The main finding of the present study was that with the exception of mental rotation, a short-term reduction in energy availability induced by diet or exercise had no effect on cognitive function in either OC users or eumenorrheic women. Accuracy in the mental rotation test, an indicator of spatial awareness, was impaired in the exercise-induced low energy availability condition only. Response time in the mental rotation test was improved to a greater extent from pre-to post-condition in OC users compared to non-users across all conditions, suggesting that reproductive hormone status may influence spatial awareness independently of energy availability.

378

379 In line with previous research (Lieberman et al. 2008; 2017), the findings of the present study suggest that for the 380 majority of components of cognition measured, performance was not significantly affected by low energy 381 availability, regardless of the method by which it was achieved. Previously, only grammatical reasoning and 382 choice reaction time were shown to be adversely affected by low energy availability when achieved through severe 383 calorie restriction and exercise (Lieberman et al. 2017). Whilst these aspects of cognitive function were not 384 directly measured in the current study, we showed no effect of low energy availability (achieved via diet or 385 exercise) on visual search test or Stroop test performance, which employ similar cognitive domains to choice 386 reaction time. These differences in findings may be due to more moderate restrictions in energy availability in the

387 current study and differences in exercise intensity and duration. A higher exercise intensity was used for a shorter 388 duration in the current study compared to previous research (Lieberman et al. 2008; 2017), whilst the dietary 389 energy intakes were higher in both the exercise-induced and diet-induced low energy availability conditions. The 390 diet and exercise regimens, and subsequent energy availability in the present study, are more representative of 391 those employed by athletes and are therefore more ecologically valid for an active population. In the present study, 392 the addition of non-exercise dietary restriction and controlled-energy balance conditions, provided the ability to 393 differentiate the effects of exercise from low energy availability, which is important as exercise can have profound 394 effects on cognitive performance (Chang et al. 2012; Tomporowski 2003) which may confound the effects of low 395 energy availability in previous studies (e.g. Lieberman et al. 2008; 2017).

396

397 This is the first study to assess the effects of low energy availability on spatial awareness (as assessed by the 398 mental rotation test) and the results showed that accuracy was significantly impaired after exercise-induced low 399 energy availability compared to the balanced energy availability condition, with no significant effects of diet-400 induced low energy availability on mental rotation performance (Figure 2). Mental rotation performance has 401 consistently been shown to be greater in athletes compared to non-athletes and therefore may be important for 402 athletic performance (Jansen and Lehmann, 2013; Jansen et al. 2012; Schmidt et al. 2016). Previous research has 403 shown that the parietal cortex is primarily involved in mental rotation tasks (Gogos et al. 2010; Milivojevic et al. 404 2009), although functional magnetic resonance imaging studies have shown no effects of energy restriction on 405 parietal cortex activation (Jakobsdottir et al. 2016). There is little evidence available on the effects of exercise on 406 parietal lobe activity, with one study showing reduced parietal operculum activation following a 20 min, 407 moderate-intensity, cycling bout (MacIntosh et al. 2014). Given that the exercise condition influenced spatial 408 awareness in the current study, further research is needed to provide mechanistic insights and assess whether such 409 changes in spatial awareness are mediated by alterations in brain activation as well as the time course of such 410 alterations. Whilst it is unclear why this cognitive domain was selectively impaired by exercise-induced low 411 energy availability, it may be that only performance on the mental rotation task was affected as this was a complex 412 task, requiring the longest processing time (mean > 2 s) of the test battery and therefore may be more susceptible 413 to interference.

414

415 The current study has improved upon previous research by not employing dietary placebos. In previous research416 (Lieberman et al. 2009, 2017), the low energy availability conditions consisted primarily of very low-calorie gels

417 or non-nutritive foods to blind participants to the condition they were undertaking. Placebo-controlled designs are 418 typically the gold-standard for randomised-controlled trials, however a series of studies have shown that dietary 419 restraint, or the conscious effort to restrict energy intake, can impair cognitive performance (Green et al. 1994; 420 Kemps et al. 2005; Rogers and Green 1993), even in the absence of changes in weight (Green and Rogers 1995). 421 Therefore, the use of placebos is not an ecologically valid model, as it may negate some of the psychological 422 consequences of consciously restricting energy intake, which would be present in real-world scenarios. The 423 present study showed that using an ecologically valid model of low energy availability has minimal effects on 424 cognitive function.

425

426 Between-group differences were shown for response time in the mental rotation test; OC users' performance 427 improved to a greater extent from pre-to post-condition compared to eumenorrheic participants. These effects 428 occurred independently of changes in energy availability as they were apparent across all conditions, so it is likely that this was a result of differing reproductive hormone profiles. Endogenous 17-β-oestradiol concentrations were 429 430 significantly reduced from pre-to post-condition in the OC users and increased (D = 0.584, moderate), albeit non-431 significantly, from pre- to-post condition in the eumenorrheic participants (group x time interaction effect, P < P432 0.05). Mental rotation performance has been shown to be inversely related to 17- β -oestradiol concentrations across 433 the menstrual cycle, which may explain these findings (Hausmann et al. 2000; Silverman and Phillips 1993). This 434 study provides further evidence of the importance of reproductive hormone concentration in spatial awareness, 435 however as this study compared change in performance over 3 days, this may provide novel evidence that 436 oestrogen influences the acquisition and/or retention of spatial awareness. These results may also be explained by 437 the eumenorrheic participants sleep quality being impaired over the 3 days compared to OC users, with sleep 438 having been shown to consolidate performance gains in mental rotation performance (Debarnot et al. 2013).

439

440 Conclusions

The current study has shown that the majority of cognitive functions are unaffected by 3 days low energy availability, irrespective of whether this is achieved through diet or exercise, in eumenorrheic women and OC users. These findings may have important implications for athletes who frequently exercise to induce a low energy availability, although further research should be conducted in elite athlete populations. This is also the first study to assess the effects of low energy availability on aspects of spatial awareness via a mental rotation task. Global accuracy on this test was negatively affected by exercise-induced low energy availability, but this effect was

447	evident at all rotation angles, and hence may not be specifically related to the mental operation of rotating visually
448	presented objects. The change in mental rotation performance over the 3 days of each condition was also different
449	between OC users and non-users, providing further evidence of the importance of oestrogen in spatial awareness
450	performance. This evidence supports the concept that low energy availability may potentially have detrimental
451	effects on aspects of physiological function other than reproductive function and bone metabolism, yet highlights
452	the importance of considering reproductive status in this area. This study has improved current understanding of
453	the effects of energy availability on cognitive performance by using ecologically valid methods of reducing energy
454	availability, and a wide range of cognitive function tests.

691 **Figure captions**

692 Figure 1. Overview of the study design adapted from Papageorgiou et al. (2018). Preliminary assessments (P)

- 693 were followed by controlled energy balance (BAL), diet-induced low energy availability (DIET) and exercise-
- 694 induced low energy availability (EX) conditions in a crossover manner. Identification (ID) of first day of menstrual
- 695 cycle or first day of pill consumption was followed by baseline testing (PRE), 3 days following a prescribed diet
- and/or exercise regimen (D1-3) and follow-up testing (POST) the morning after day 3 of the condition. Dietary
- 697 energy intake (DEI), exercise energy expenditure (EEE) and energy availability (EA) are described for each
- 698 condition proportionate to lean body mass (LBM). All groups (eumenorrheic, OC users) completed both time
- 699 points (PRE, POST) for all conditions (BAL, DIET, EX) in separate menstrual or oral contraceptive cycles.
- **Figure 2**. Mean ± 1SD percentage change in overall accuracy in the mental rotation test for controlled energy
- balance (BAL), diet-induced low energy availability (DIET) and exercise-induced low energy availability (EX).
- * indicates a significant difference between BAL and EX (P < 0.05).
- **Figure 3.** Mean ± 1SD change in score on the Brunel Mood Scale (BRUMS) from pre- to post-condition for
- controlled energy balance (BAL), diet-induced low energy availability (DIET) and exercise-induced low energy
- availability (EX). * indicates a significant difference between conditions (P < 0.05).
